ABSTRACT

The UKIDSS Galactic Plane Survey (GPS) is one of the five near infrared Public Legacy Surveys that are being undertaken by the UKIDSS consortium, using the Wide Field Camera on the United Kingdom Infrared Telescope. It is surveying 1868 $\deg^2$ of the northern and equatorial Galactic plane at Galactic latitudes $-5° < b < 5°$ in the J, H and K filters and a $\sim 200 \deg^2$ area of the Taurus-Auriga-Perseus molecular cloud complex in these three filters and the 2.12 μm (1-0) H_2 filter. It will provide data on $\sim 2 \times 10^9$ sources. Here we describe the properties of the dataset and provide a user's guide for its exploitation. We also present brief Demonstration Science results from DR2 and from the Science Verification programme. These results illustrate how GPS data will frequently be combined with data taken in other wavebands to produce scientific results. The Demonstration Science comprises six studies. (1) A GPS-*Spitzer*-GLIMPSE cross match for the star formation region G28.983-0.603 to identify YSOs. This increases the number of YSOs identified by a factor of ten compared to GLIMPSE alone. (2) A wide field study of the M17 nebula, in which an extinction map of the field is presented and the effect of source confusion on luminosity functions in different sub-regions is noted. (3) H_2 emission in the ρ Ophiuchi dark cloud. All the molecular jets are traced back to a single active clump containing only a few protostars, which suggests that the duration of strong jet activity and associated rapid accretion in low mass protostars is brief. (4) X-ray sources in the Nuclear Bulge. The GPS data distinguishes local main sequence counterparts with soft X-ray spectra from Nuclear Bulge giant counterparts with hard X-ray spectra. (5) External galaxies in the Zone of Avoidance. The galaxies are clearly distinguished from stars in fields at longitudes $l>90°$. (6) IPHAS-GPS optical-infrared spectrophotometric typing. The *(i'-J) vs.(J-H)* diagram is used to distinguish A-F type dwarfs, G dwarfs, K dwarfs and red clump giants in a field with high reddening.

Key words: survey; methods: data analysis; stars: formation; (stars:) circumstellar matter; Galaxy: stellar content

1   INTRODUCTION

The United Kingdom Infrared Deep Sky Survey (UKIDSS) is a suite of five public surveys of varying depth and area coverage which began in May 2005 and are expected to continue until 2012. These surveys all use the Wide Field Camera (WFCAM, see Casali et al.2007) on the United Kingdom Infrared Telescope (UKIRT). The design and the principal aims of the five UKIDSS surveys are described by Lawrence et al. (2007), along with a brief example of data from each survey. The data are reduced and calibrated at the Cambridge Astronomical Survey Unit (CASU) using a dedicated software pipeline (Irwin et al.2008) and are then transferred to the WFCAM Science Archive (hereafter the WSA, Hambly et al.2008) in Edinburgh. There, the data are ingested into a sophisticated SQL database and detections in the different passbands are merged.

The UKIDSS data are released as SQL databases at intervals of six to twelve months. The area coverage and data quality of these releases are described by Dye et al.(2006, the Early Data Release), Warren et al.(2007a, the First Data Release) and Warren et al.(2007b, the Second Data Release). In addition to the major releases, smaller batches of pipeline processed images and their associated FITS binary source catalogues for individual passbands are released on a faster timescale, but with no quality control. The raw data are available through CASU and the ESO archive. The UKIDSS data are presently public to all professional astronomers in any ESO member state. World access to the various data releases begins 18 months after each data release to ESO.[1]

The aim of this paper is to provide a guide to the GPS database in the WSA. We describe the properties of the data in detail, illustrating usage of the WSA tools and giving examples of how to combine GPS data with data from other wavebands for maximum scientific benefit. This should be regarded as essential reading for those wishing to exploit the data. This paper describes the main GPS-specific aspects of the UKIDSS database in one place. We note that neither the pipeline nor the WSA were designed explicitly for the GPS but rather for the UKIDSS surveys as a whole. Some compromises were made to produce an efficient database in a reasonable period of time and we describe their effects here.

The paper is structured as follows. In §2 we summarize the survey design, including recent changes from the original plan described by Lawrence et al. In §3 we describe the properties of the GPS dataset (depth and stellar populations) as a function of Galactic location and source confusion. In §4 we present Demonstration Science results from the Science Verification programme and from DR2 that are designed to illustrate the variety of uses of GPS data, in combination with data from other wavebands. Finally, Appendix A contains a detailed guide to the WSA for GPS science. The guide illustrates how to use the parameters available in the GPS database to best effect and describes the strengths and weaknesses of the data that are presently available.

[1] Users can obtain a WSA account through their local Community Administrator at their home institution. If the institution has no UKIDSS community then they should contact the Consortium Survey Scientist, currently Steve Warren (email: s.j.warren@ic.ac.uk)

2   SUMMARY OF GPS STRATEGY, AREA AND INTEGRATION TIME

The GPS is designed to cover the entire northern and equatorial Galactic plane that is accessible to UKIRT in a 10 degree wide band around the sky. There is also a narrower southern extension to the Galactic Centre and a 200 deg^2 survey of the Taurus-Auriga-Perseus (TAP) molecular cloud complex, which lies off the plane and follows the contours of the ^{13}CO gas mapped by Ungerechts & Thaddeus (1987). The southern extension is narrower because of its poorer accessibility from Mauna Kea. In Galactic coordinates, the in-plane region is: $141 < l < 230$, $-5 < b < 5$; $15 < l < 107$, $-5 < b < 5$; and $-2 < l < 15$, $-2 < b < 2$. The section of the plane at l=107 to 141 is not covered because it lies north of Dec=$+60°$, a region of the sky that UKIRT cannot reach due to fundamental features of the telescope design.

Observations are made in the J, H and K bandpasses with total on-source integration times of 80s, 80s and 40s respectively. These integrations are made up of shorter exposures, employing a sub-pixel dithering strategy to fully sample the image profile (see §A1.2). WFCAM has four spatially separated arrays, so a tiling strategy is employed to obtain images of contiguous areas of the sky (see §A1.1). The median 5σ depths in DR2 given by Warren et al.(2007b) are J=19.77, H=19.00, K=18.05 (Vega system). However, the survey depth is spatially variable due to source confusion so these figures should be used with caution, see §3. Data in the three filters are generally collected within an interval of 20 minutes for any point on the sky, in order to minimise the effects of any photometric variability on source colours and derived extinction. Exceptions can occur (in DR2 and later releases) when data that failed quality control in only one or two filters were later repeated in only those filters. In these cases there will always be near contemporaneous fluxes in at least two filters which can be used to estimate intrinsic source colours and extinction. The TAP molecular cloud component of the survey also includes observations in the 2.12 μm (1-0) S(1) H$_2$ filter, with a total on source integration time of 160s.

The data reduction pipeline is described in Irwin et al.(2008), so we do not provide a full description here. Some of the more significant details that may affect the data in unexpected ways are described in §A2. One important aspect of the reduction that is worth reiterating here is the photometric calibration. The photometric zero points are bootstrapped from the 2MASS Point Source Catalogue, which is believed to provide a reliable photometric calibration over the whole sky (Skrutskie et al.2006). If we assume that the 2MASS calibration is perfect, the scatter in the derived zero points for the numerous 2MASS stars used in each WFCAM field indicates that the absolute accuracy of the UKIDSS photometric calibration in the J, H and K bandpasses is 1-2% in photometric conditions and 2-3% in non-photometric conditions (Hodgkin et al., 2008, submitted). Since the 2MASS J, H and Ks filters are slightly different from the WFCAM filters (see Hewett et al.2006), photometric transformations are used to correct the zero points. From DR2 onward, these transformations include extinction terms to correct for the fact that the colours of stars in the Galactic plane are influenced by interstellar reddening as well as temperature and gravity (Warren et al.2007b). These

transformations are included in §A2 for completeness. They should be used in preference to the preliminary transformations given in Hewett et al.(2006).

UKIDSS astrometry is also calibrated using numerous bright 2MASS stars in each field. The precision of the astrometric solution is typically 0.09 arcsec for GPS data, as determined from the r.m.s. residuals of the stars to the fit (see §A1.3 for details of how to determine the precision for specific fields). Individual stars can of course have much less precise astrometry, owing to source confusion or low signal to noise ratio.

Owing to source confusion the survey depth is spatially variable in the more crowded parts of the plane (see §3.1). Hence, in many regions of the plane the GPS represents the deepest survey possible with ground based, seeing limited wide field instrumentation. Deeper images can be obtained by using higher resolution cameras with smaller pixels in conditions of good seeing, but for the foreseeable future such cameras will not be able to cover large areas of the Galactic plane.

The sky coverage in the various data releases so far is described in the references given in §1. Those areas of the plane at $-2 < l < 107$ with three band coverage can be viewed as an interactive three colour mosaic at http://surveys.roe.ac.uk:8080/wsa/gps_mosaic.jsp, (credit M.Read) where the finest spatial scale has $1''$pixels.

2.1 Changes to the GPS Programme

In early 2007 there was a review of the UKIDSS project in response to a call for additional large observing proposals. This led to changes and reductions in the UKIDSS programme in order to accomodate the new observing campaigns. The original GPS design (Lawrence et al.2007) also included two additional epochs of data in the K band only, which were intended to provide a long time baseline for proper motions and to detect high amplitude variable stars. Following the 2007 review, further progress on these K-only scans of the survey area has been deferred until at least 2010. Some 500 $\deg^2$ of the plane have already been observed in the K-only mode during conditions of thin cirrus cloud (defined as <20% drop in throughput), covering regions not yet observed in the main three band survey. Since the UKIDSS photometry is calibrated using numerous 2MASS sources in every field there is only a very small loss of precision for relative photometry (at the millimagnitude level) even when observing through thin cirrus (Hodgkin et al.2008). The main JHK survey has been conducted in photometric conditions, in order to ensure maximum depth, but thin cirrus conditions (<10% absorption) may be accepted from late 2008 in order to assist timely completion of the survey.

It was originally planned to observe a region 300 $\deg^2$ of TAP molecular clouds three times: once in the J, H, K and H_2 filters and twice more in the K and H_2 filters, in order to measure the velocities and accelerations of protostellar jets. However this part of the survey was cancelled in the 2007 review of UKIDSS, at which point ∼150 $\deg^2$ of the region had been observed. Nonetheless, the remainder of the TAP region will observed in the Z, Y, J, H and K filters as part of the ongoing UKIDSS Galactic Clusters Survey, which included the same region. Observations of the TAP region with the H_2 filter are continuing via Directors Dis-

cretionary Time and small observing programmes, with the aim of completing one pass of the denser cloud cores, with a total area of ∼200 $\deg^2$. The TAP area coverage is described in more detail in Davis et al.(2008), and the reduced data can be viewed at www.jach.hawaii.edu/UKIRT/TAP.[2]

3 POPULATIONS AND DATA PROPERTIES AS A FUNCTION OF GALACTIC COORDINATES

In this section we present magnitude histograms, colour magnitude diagrams and two colour diagrams for representative fields throughout the survey region. We discuss the survey depth as a function of Galactic coordinates and then describe the nature of the main Galactic (and extragalactic) populations that are detected. The Besançon Galactic stellar population model[3] (Robin et al.2003) is used to help interpret the diagrams and we then compare some diagrams for the synthetic population with the real data.

Figures 1 to 13 show the results for 12 GPS fields. The fields at $l < 90°$ are square boxes that are 0.2 degrees on a side in l and b. The fields at $l > 90°$ are square boxes that are 0.5 degrees on a side in l and b, in order to provide similar sized samples to reveal the nature of the populations in these less crowded regions. All fields include data from at least 2 spatially separate WFCAM multiframes and usually more. Any errors in global photometric calibration would add to the scatter in these plots. However the quality of the 2MASS-based photometric calibration is such that we see no obvious increase in scatter compared to data from individual WFCAM arrays.

### 3.1 Survey sensitivity and the effect of source confusion

Figure 1 shows the magnitude histograms. Visual inspection of the images shows that the fields at $l > 90°$ have less source confusion than the other fields and source confusion is insignificant for the two fields near $l=170°$. The corresponding histograms represent the maximum intrinsic depth of the survey. We see that the modal depths in uncrowded fields are approximately K=17.75 to 18.0, H=18.5 to 18.75, J=19.4 to 19.65. The variation is due to the variable seeing, sky brightness, thermal background and atmospheric transparency during the survey. These modal depths are slightly shallower than the 5σ depths quoted in §2: K=18.05, H=19.00, J=19.77. The reasons for this are described in §A3. By visually extrapolating the histograms and assuming that the decline at faint magnitudes is entirely due to limited sensitivity we estimate that the typical 90% completeness

---

[2] To gain access to this web page, UKIDSS members should request the user name and password from Chris Davis, email: c.davis@jach.hawaii.edu. The data become world public 18 months after release to UKIDSS members.
[3] The Besançon models are available on-line at bison.obs-besancon.fr/modele
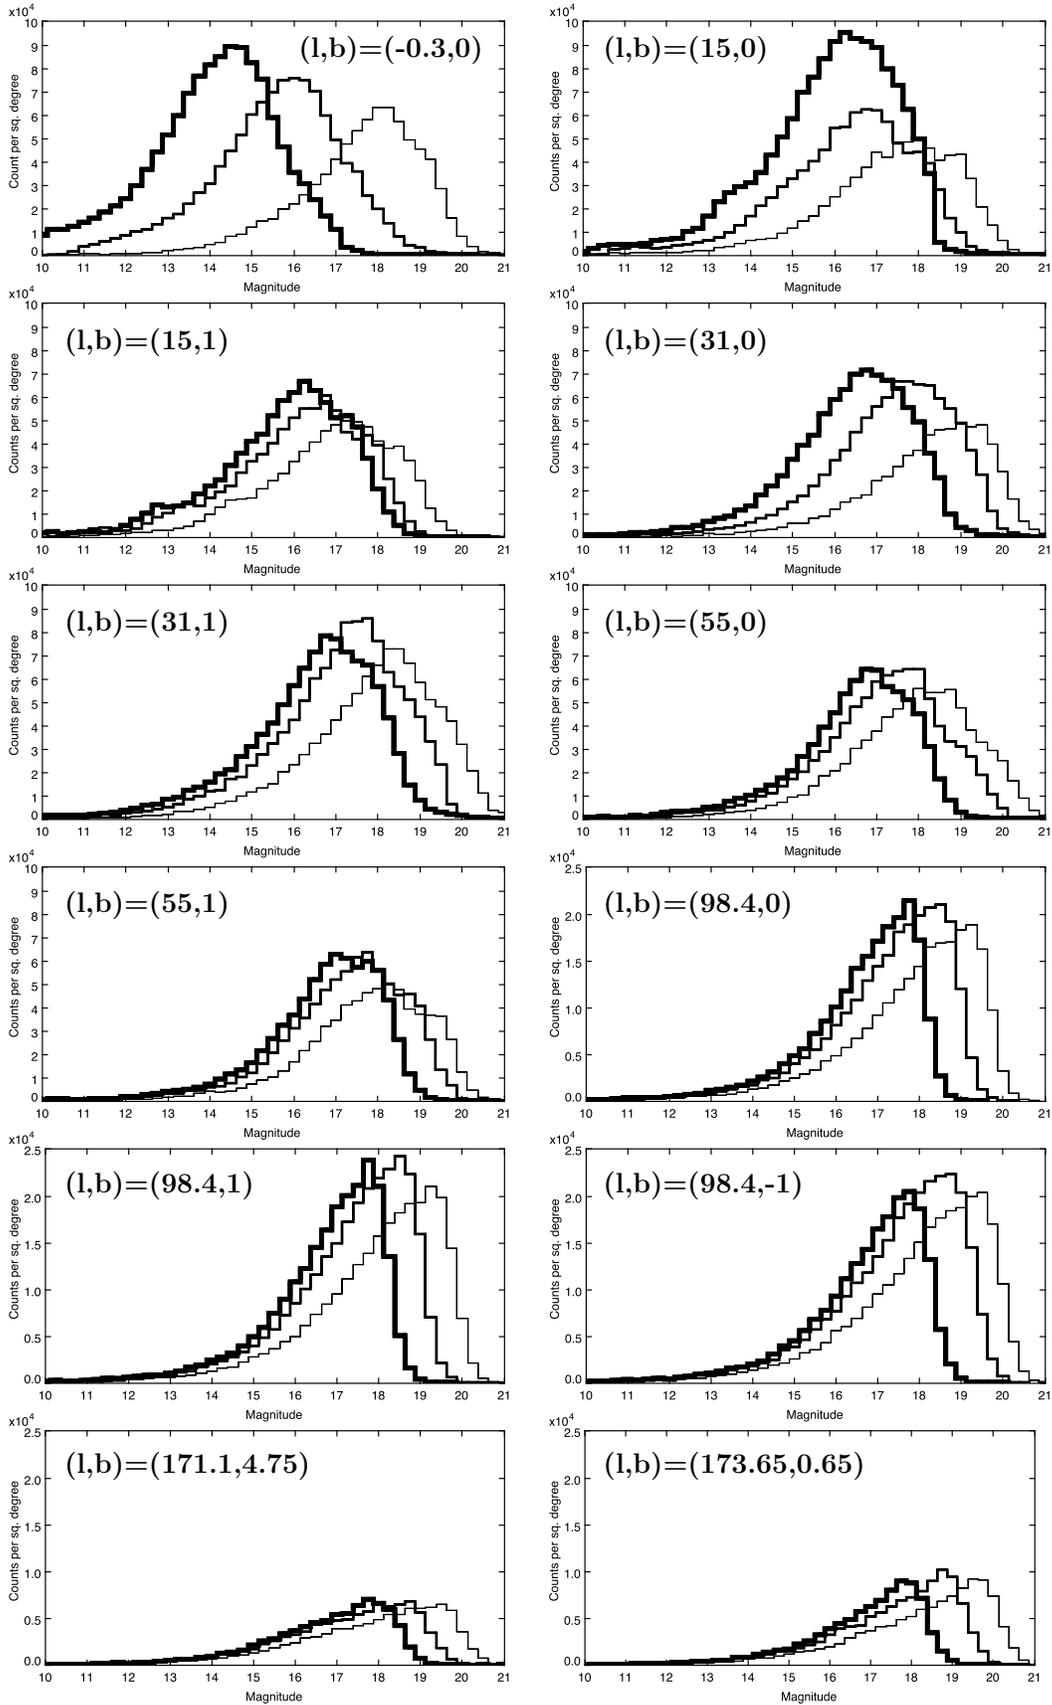

Figure 1. Magnitude histograms in a selection of GPS fields. Thick lines: K band; medium lines: H band; thin lines: J band. A linear scale is used rather than the conventional log scale in order to better illustrate the observed variation in modal magnitude between fields. Source counts per square degree are given, using bins of width 0.25 magnitudes. A general decline in source density is seen with increasing longitude and increasing distance from the mid-plane, though there are some exceptions to this trend.
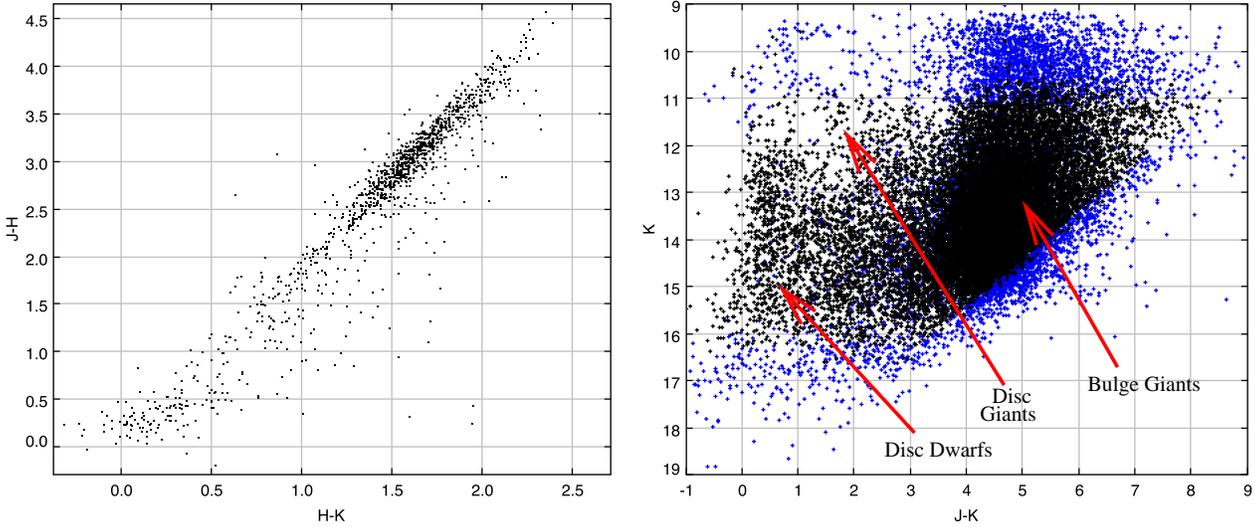

Figure 2. (l, b)=(-0.3,0). Colour magnitude and two colour diagrams for a 0.2×0.2° field adjacent to the Galactic centre. The two colour diagram, like those in figures 3 to 13, shows only sources with the "most reliable, low completeness" selection described in §A3. By contrast, the colour magnitude diagram, as in figures 3 to 13, shows all sources except "noise" detections. Sources with "unreliable photometry" (see text §3.2) are marked in blue. Both diagrams are dominated by the highly reddened Bulge population. The less reddened sequences of disk dwarfs and disk red clump giants are also visible in the colour magnitude diagram but less clearly than in figures 3 to 13.

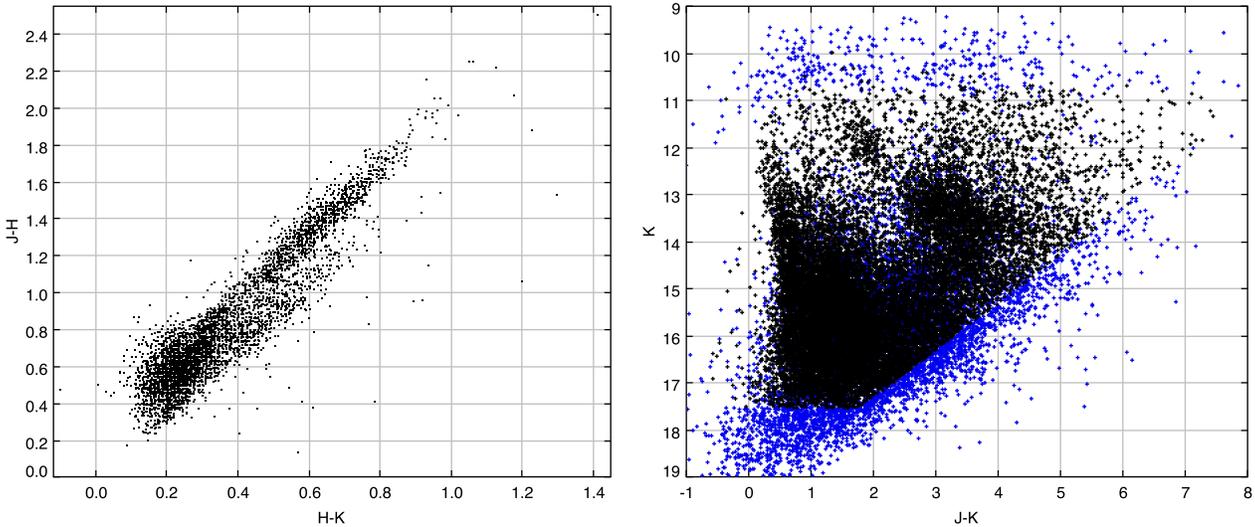

Figure 3. (l, b)=(15,0). This crowded field in the inner Galactic mid-plane shows a well defined dwarf sequence at the left of the colour magnitude diagram and a diagonal red clump giant sequence to the right of it. The two colour diagram shows a distinction between giants and dwarfs. Both luminosity classes form sequences parallel to the reddening vector but giants have redder *(J-H)* colours than the dwarf sequence underneath (see text §3.2). The points plotted are selected in the same way as in figure 2.

limits in uncrowded fields are located at K=18.0, H=18.75, J=19.5, with uncertainties of about 0.2 magnitudes. Individual fields in the outer Galaxy should always be within 0.3 magnitudes of these typical values, since only a modest range of observing conditions (seeing and transparency) is permitted, as described in the data release papers. We do not attempt a more precise quantification of the mode and spread of the sensitivity at this stage since there is limited data for the outer Galaxy in DR2, and the sensitivity in future data releases is likely to change slightly. The seeing conditions required to begin an observation at l >107° were relaxed from a maximum FWHM of 0.8 arcsec (measured in

the K bandpass) to 1.0 arcsec from February 2007 in order to speed the survey progress.

It is clear that the survey is much less sensitive near the Galactic centre than in uncrowded fields. However the 90% completeness limits and modal magnitudes are usually degraded by no more than 1 magnitude in fields at l >30°, even in the mid-plane at b=0°.

The effects of extinction on the histograms are apparent in the change in the relative numbers of J, H and K band detections in different parts of the Galaxy. The K band source density is the highest in the fields at l <30°. At l >30° the H band source density is higher (at least for the fields
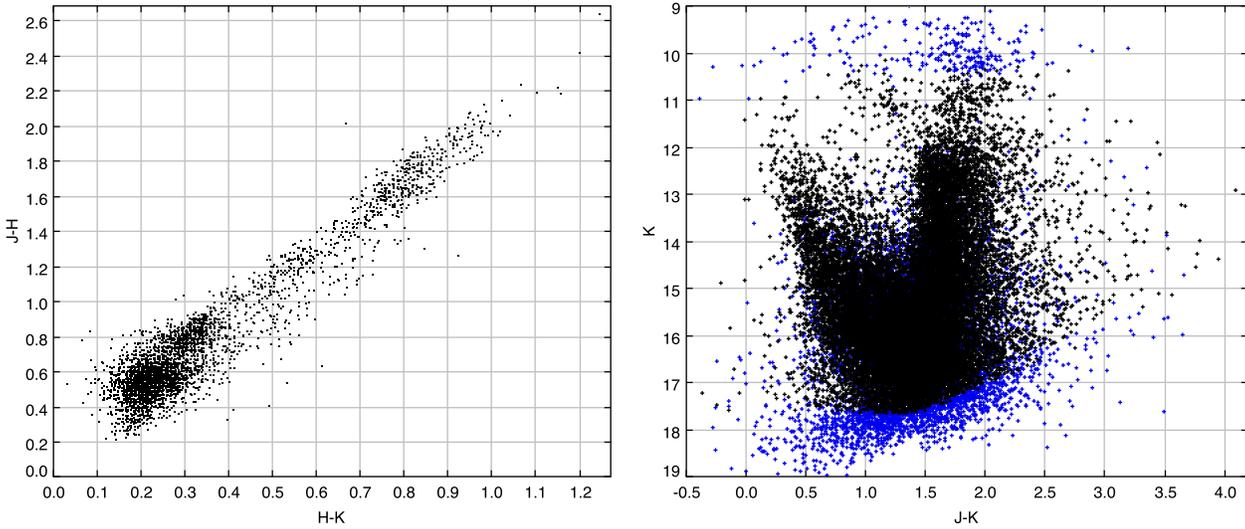

Figure 4. (l,b)=(15,1). The red clump giants form a diagonal sequence in the colour magnitude diagram, from m$_K$=10.5 to 12, *(J-K)*=0.8 to 1.7, which then becomes approximately vertical at fainter magnitudes. This field is on a line of sight that gradually rises above the Galactic plane at large heliocentric distances. This leads to reduced extinction at large distances (see text §3.2 and figure 15), which explain the change in slope of the giant sequence at faint magnitudes. A substantial Bulge giant population is also seen to the right of the diagonal red clump giant sequence at m$_K$ < 12. The two giant populations appear to merge at fainter magnitudes. The reddening sequences in the two colour diagram are shorter than in figure 3. The points plotted are selected in the same way as in figure 2.

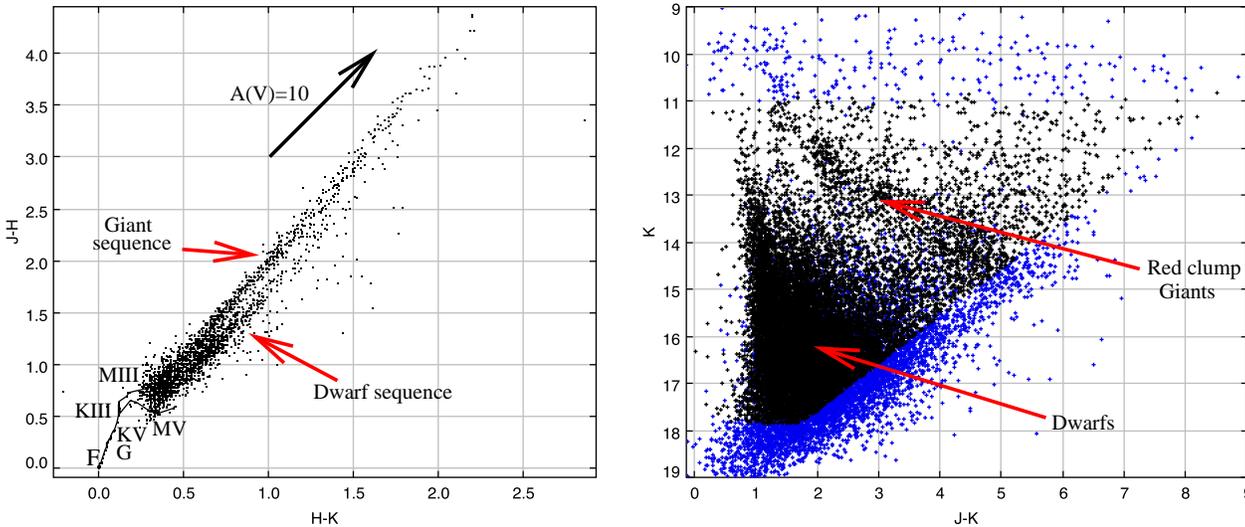

Figure 5. (l,b)=(31,0). The field shows very clearly defined dwarf and giant reddening sequences in the two colour diagram. The colours of unreddened stars from Hewett et al.(2006) are indicated by the solid lines, with approximate spectral types marked. The reddening vector of Rieke & Lebofski (1985) is overplotted. The colour magnitude diagram shows that the Bulge giant population has disappeared at this longitude, while the disk red clump giant population follows a winding diagonal sequence, indicating variable reddening along the line of sight. The points plotted are selected in the same way as in figure 2.

at $|b|$ <1° for which multi-band data presently exist). The source density in the J band becomes comparable to the H band at l >90°.

3.2 Stellar and extragalactic populations

The two colour diagrams and colour magnitude diagrams in figures 2-13 allow us to clearly identify the main stellar populations detected in the GPS and detect changes in extinction as a function of distance along different lines of sight. Some readers will be familiar with similar diagrams constructed

from data in the DENIS and 2MASS surveys (e.g. Ojha et al.2000) or from surveys of the stellar populations in external galaxies. In general, the populations detected by the GPS consist of less luminous stars than those in most previously published wide field infrared surveys. Consequently, the diagrams look quite different and their interpretation is often less obvious than might be supposed. We have chosen to plot K vs. *(J-K)* colour magnitudes since the other near infrared colours (*(J-H)* and *(H-K)*) provide less separation between the various stellar populations and add little to this discussion. In general, near infrared diagrams can
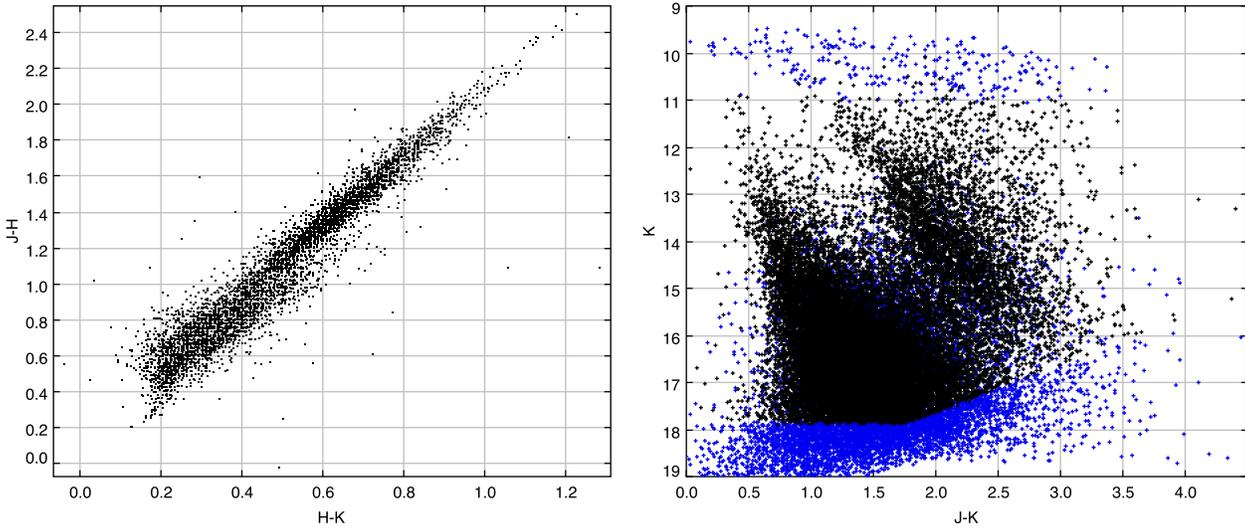

Figure 6. (l, b)=(31,1). The two colour diagram is similar to that for (l, b)=(15,1). However, the colour magnitude diagram shows a diagonal red clump giant branch that does not become vertical at faint magnitudes. This suggests that this line of sight passes through a region of the galaxy in which stars are located above the plane, perhaps due to a warp. The points plotted are selected in the same way as in figure 2.
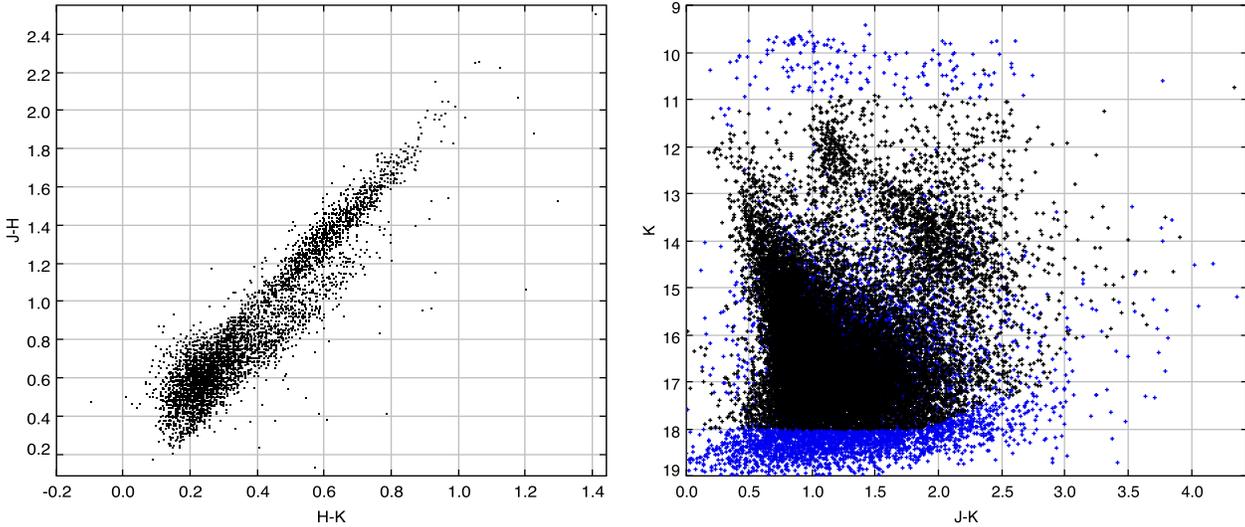

Figure 7. (l, b)=(55,0). This field shows an abrupt change in the slope of the disk red clump giant branch in the colour magnitude diagram at m_K=13, indicating the presence of a discrete cloud of dense interstellar gas and dust. The points plotted are selected in the same way as in figure 2.

separate the nearby late dwarf, distant early dwarf, and red giant populations, with more complex behaviour depending on the sightline.

In this section we first summarise the general properties of the two colour diagrams and then discuss the colour magnitude diagrams, beginning with the inner Galactic fields.

The two colour digrams for the inner Galactic fields in figures 2 to 8 all show two parallel sequences of stars extending from the lower left to the upper right. The upper sequence is composed mainly of giants (mostly of the type known as "red clump giants") while the lower sequence consists of dwarf stars. These long sequences are due to interstellar reddening: they lie *approximately* parallel to the reddening vector and can be used to estimate the interstel-

lar extinction toward each star by comparing the observed colours with those of unreddened stars. The colours of a sample of unreddened main sequence and giant stars from Hewett et al.(2006) are plotted in figure 5 for illustration, along with the reddening vector of Rieke & Lebofsky (1985). Late type giants have $\sim$0.15-0.3 mag larger *(J-H)* colours than dwarfs of the same spectral type, due to the effect of their low surface gravities on the opacity of the H$^-$ molecular ion. The more distant dwarfs also tend to have earlier spectral types than the giants, which also contributes to the difference in *(J-H)* colours.

A careful inspection of the reddened sequences of stars in the two colour diagrams shows that they are not quite straight lines. This is due to two effects. The first is that
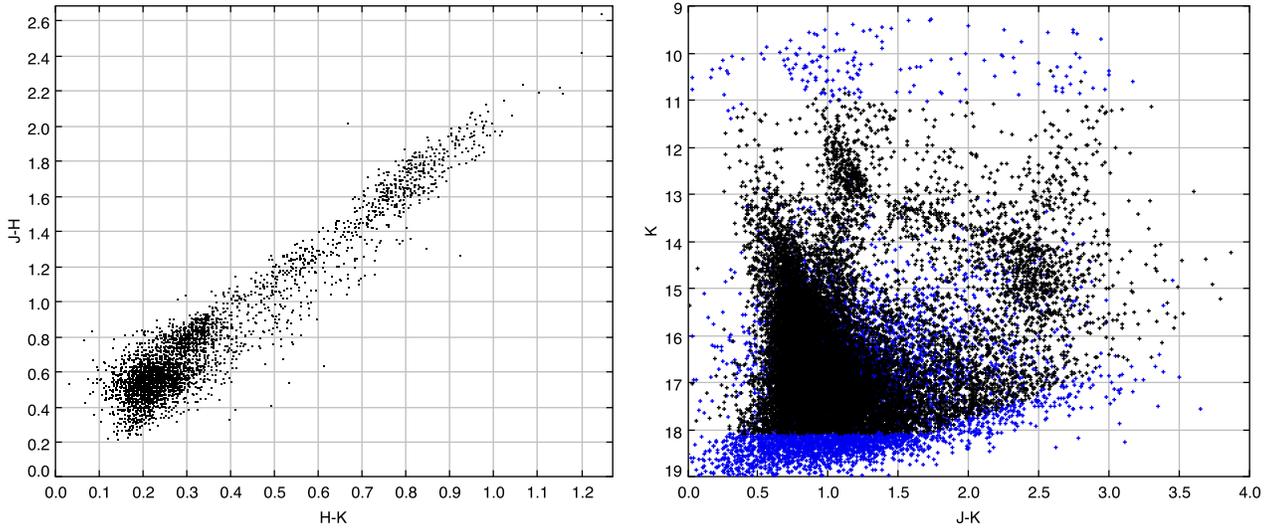

Figure 8. (l, b)=(55,1). This field shows a very strong discontinuity in the slope of the disk red clump giant branch in the colour magnitude diagram at m_K=13 to 14, where the *(J-K)* colour increases from 1.2 to 2.4. This indicates the presence of a discrete cloud of dense interstellar gas and dust (see text §3.2). This may be related to the weaker feature in figure 7. At fainter magnitudes the giant sequence become vertical, indicating that the line of sight has risen above the plane to a region of low interstellar extinction. Note that the sequence of late K and M dwarfs (see text §3.2) becomes visible at m_K=13 to 14.5, *(J-K)*=1.0. It protrudes from the bulk of the earlier type disk dwarfs at the left hand side and extends up toward the giant branch. The points plotted are selected in the same way as in figure 2.

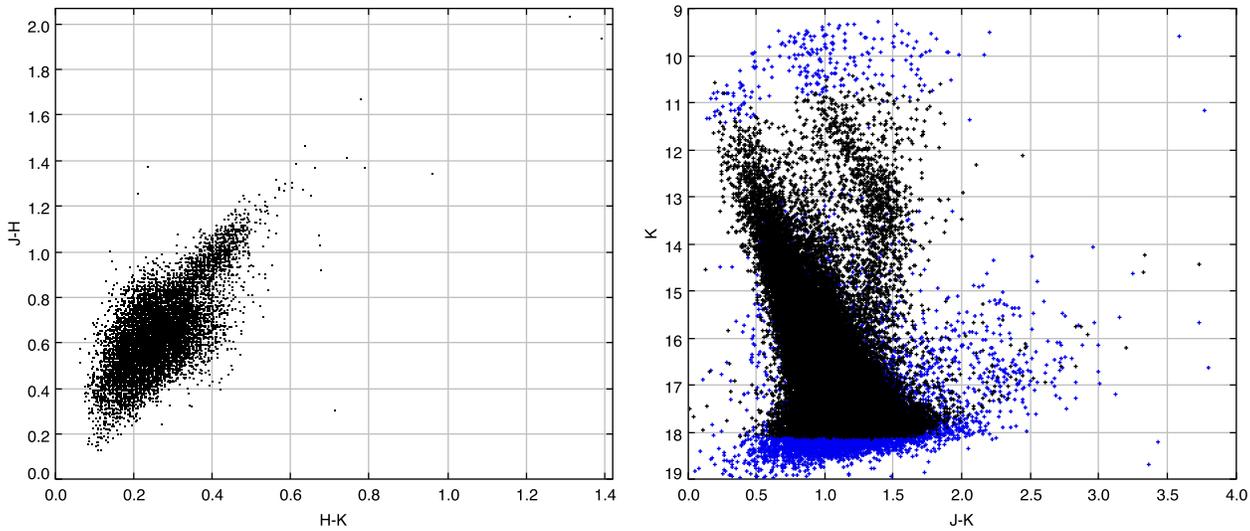

Figure 9. (l, b)=(98.4,0). The field lies in the outer galaxy and the extinction is now clearly less than in figures 2 to 8, as evidenced by the shorter reddening sequence in the two colour digram. A 0.5×0.5 degree field is plotted here and for the other outer Galaxy fields in order to maintain sufficient source counts to define the populations clearly. The giant branch in the colour magnitiude diagram becomes vertical at m_K >13. This indicates a lack of additional extinction at large heliocentric distances in the mid-plane, which is attributed to the northern Galactic warp. Note the population of external galaxies that is visible at lower right ($(J-K)$>2). These are mostly marked in blue because they are spatially resolved, and therefore fall into our "unreliable photometry" category, even though their fluxes in the 2″aperture are well measured. The points plotted are selected in the same way as in figure 2.

the nature of the detected stellar population shifts towards more luminous stars with increasing distance and reddening. The clump of stars seen at the lower left of most of the two colour diagrams is composed mainly of nearby G, K and early M type dwarfs, which have a high space density. As we move further along the dwarf sequence the population shifts towards early G, F and A type dwarfs, which have a lower space density but are detected at larger distances.

The dwarf sequence ends at a lower reddening than the giant sequence because the dwarfs are less luminous. This change in populations means that the the dwarf sequence has a slightly shallower gradient than the reddening vector. The second reason that the gradient is not linear is that the effective bandpasses of the filters change with increasing reddening when observing a continuum source, so reddening vectors become curved as the extinction increases (e.g. Kaas
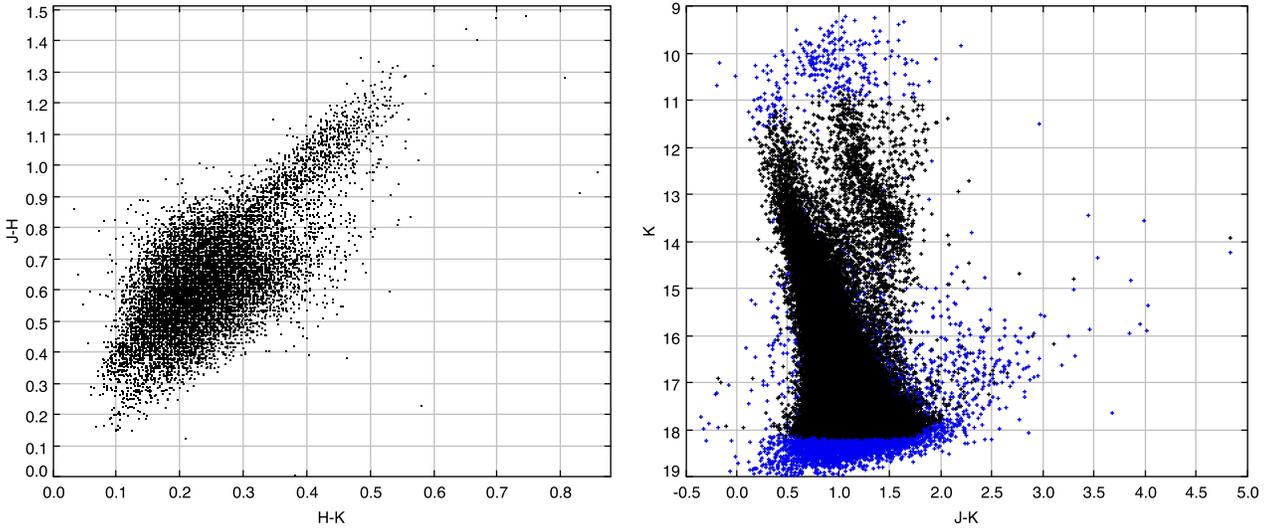

Figure 10. (l, b)=(98.4,1). The diagrams for this field appear very similar to those for (l, b)=(98.4,0), in term of reddening. This is consistent with expectations due to the presence of the northern warp, which creates an overdensity of stars and interstellar extinction above the plane at large Galactocentric distances, relative to what would be expected if the outer Galaxy were centred in the plane. The points plotted are selected in the same way as in figure 2.

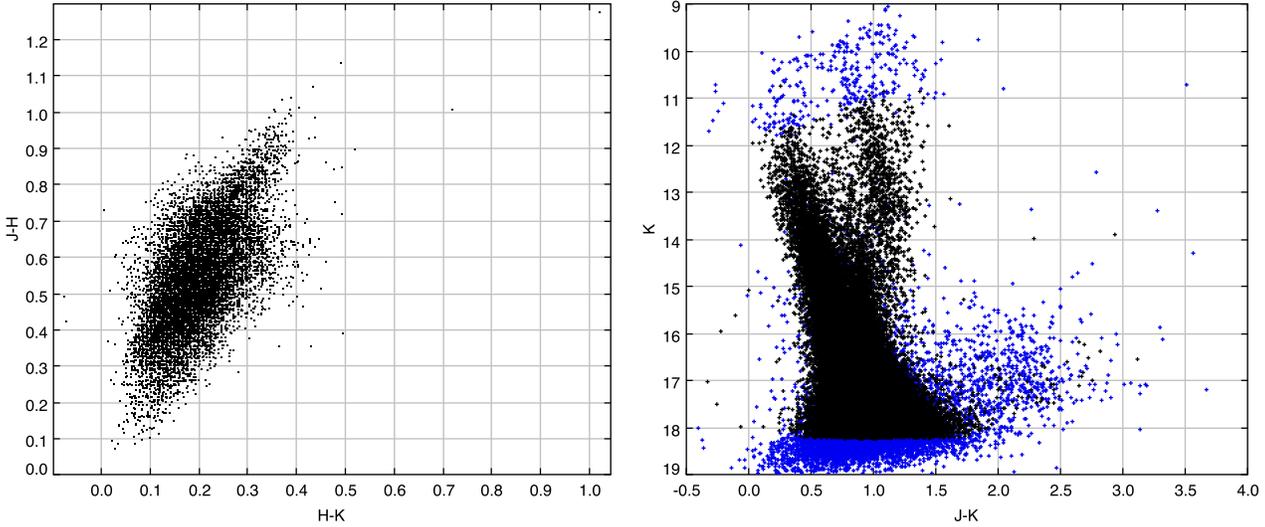

Figure 11. (l, b)=(98.4,-1). This field on a line of sight below the mid-plane shows reduced reddening compared to figures 9 and 10, since the overdensity due to the warp is located at positive latitudes. The external galaxy population remains visible at lower right in the colour magnitude diagram and the late K and M dwarf dwarf sequence is faintly visible at m_K=12.6 to 14.5, $(J-K)$=0.7, between the bulk of the FG dwarf sequence and the giant branch. The points plotted are selected in the same way as in figure 2.

et al.1999). The precise form of the curve differs for sources with different spectra, so there is no universal reddening vector, see e.g. Drew et al.(2005). The giant sequence generally begins at a slightly higher reddening than the clump of nearby late type dwarfs, since giant stars have a lower space density. This population can in principle be used to measure the reddening curve for red clump giants. In general a standard linear interstellar reddening vector is adequate for most applications and this approach is used in this work. A more sophisticated approach using a model of the instrumental transmission and stellar model atmospheres will be developed in a future paper on Galactic structure.

All of the two colour diagrams show samples selected using the least complete, most reliable selection described in §A3, with errors <0.05 mag in the colours on each axis, in order to distinguish the closely spaced stellar populations. Including fainter sources with less precise photometry simply increases the scatter in the diagrams, as shown in figure A1(a), and extends the dwarf and giant sequences to slightly higher reddening values at the upper right.

By contrast, the colour magnitude diagrams show all the three band detections within the chosen axis ranges, except those classified as "noise" detections (see §A3). Sources with more reliable photometry are shown in black, while sources with less precise photometry are shown in blue. Sources are put in the "less precise" selection if they fail to satisfy any of the following criteria. (1) Photometric uncertainties <0.2 mag in the two bands used in each dia-
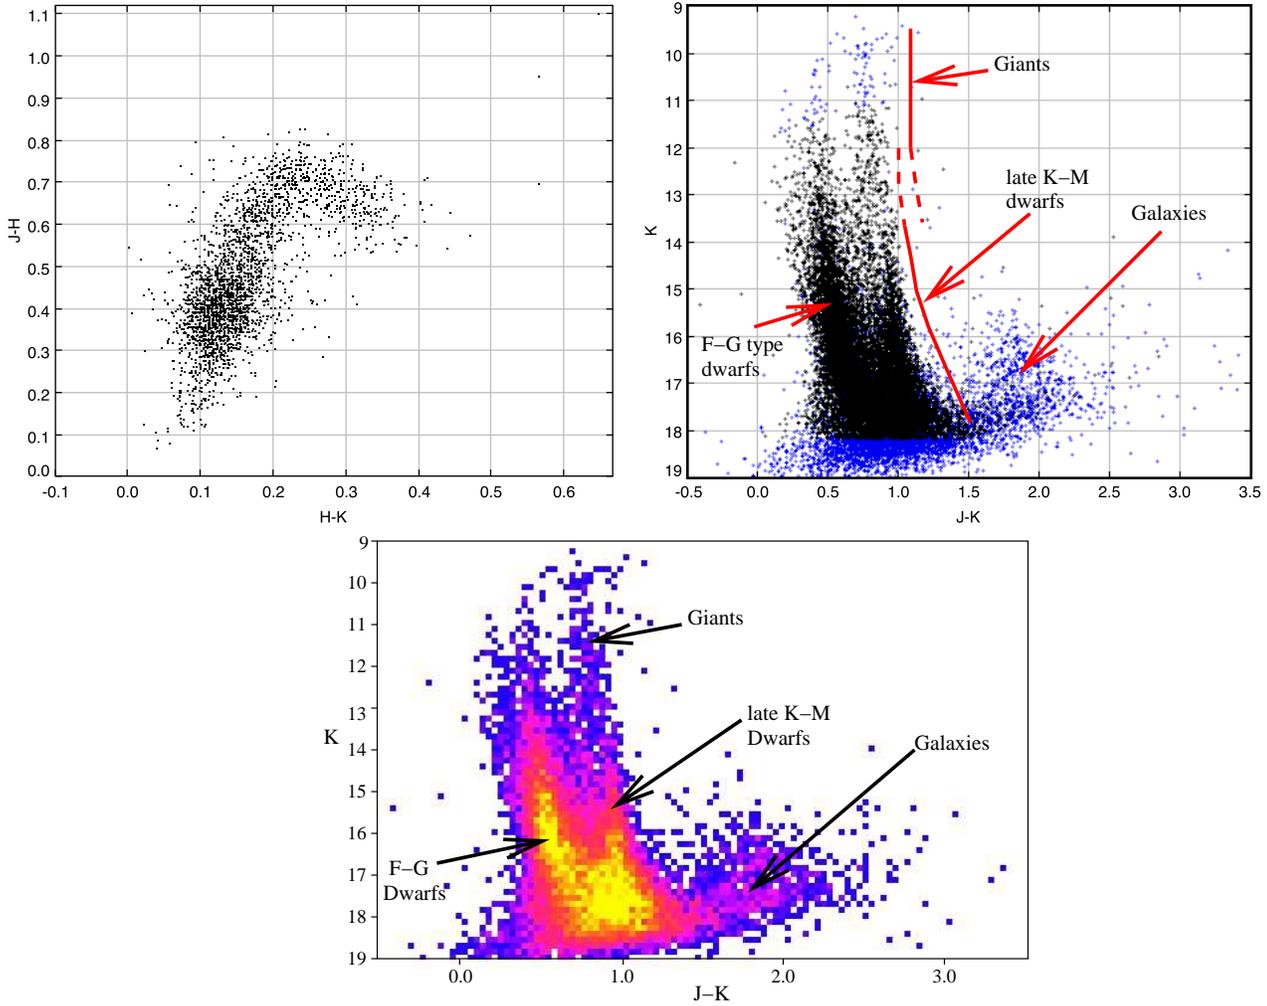

Figure 12. $(l, b)=(171.1, 4.75)$. This field lies on a line of sight almost directly opposite the Galactic centre and $4.75°$ off the plane. The stellar populations are very different from those in figures 2 to 10: the right hand sequence of stars in the colour magnitude diagram is now dominated by nearby late K and M dwarfs, as opposed to red clump giants. Giants are more numerous than late K and M dwarfs only at $m_K \lesssim 13$, but they are not clearly distinguished from the dwarfs in the colour magnitude diagram. The left hand sequence is dominated by F and G dwarfs. The rapid change in *(J-K)* colour with spectral type among late G and early K dwarfs causes the gap between the sequences (see figure 14). The lower panel shows a density map of the colour magnitude diagram (a "Hess diagram"). It shows that the two sequences join at faint magnitudes, where the early K types are more numerous and there also is a larger population of late K and early M dwarfs. The two colour diagram shows that there is little reddening in this field. The points plotted are selected in the same way as in figure 2.

gram. The corresponding less precise sources are faint objects lying in a group at the bottom of each diagram. (2) `ppErrbits`<256. This parameter is decribed in §A3. Most sources failing this criterion do so because they are flagged as close to saturation, and therefore lie in a group at the top of each diagram. Inspection of the diagrams shows that they nonetheless often play a valuable role in defining the different stellar populations, indicating that the errors in their photometry need not be extreme. (3) `pstar`>0.9. Sources only fail this criterion if they appear significantly non-stellar in at least one of the three passbands, usually because they are either part of a marginally resolved stellar pair or a resolved external galaxy. Marginally resolved stellar pairs are evenly spread among the sources with more reliable photometry but extend further to the left and right sides of the diagrams. The resolved galaxies are located in a group at

the lower right of the colour magnitude diagrams. The extragalactic group is clearly seen only in the fields at $l > 90°$.

The colour magnitude diagrams all show at least two principal sequences of stars. On first inspection, one might suppose that these correspond to luminosity class V dwarfs on the left side of the diagrams and luminosity class III red clump giants on the right. This is indeed the case for the inner Galactic fields, which we will now discuss. However, the situation is more complicated in the outer Galaxy, as we shall see later.

The main feature of the colour magnitude diagrams for l=15, 31, 55 and 98.4 (see figures 3 to 11) is the division into two principal sequences corresponding to dwarfs on the left and giants on the right. The Besançon model indicates that the majority of the giants are K1III-K2III types. These stars occupy a sharp and well defined peak in the absolute
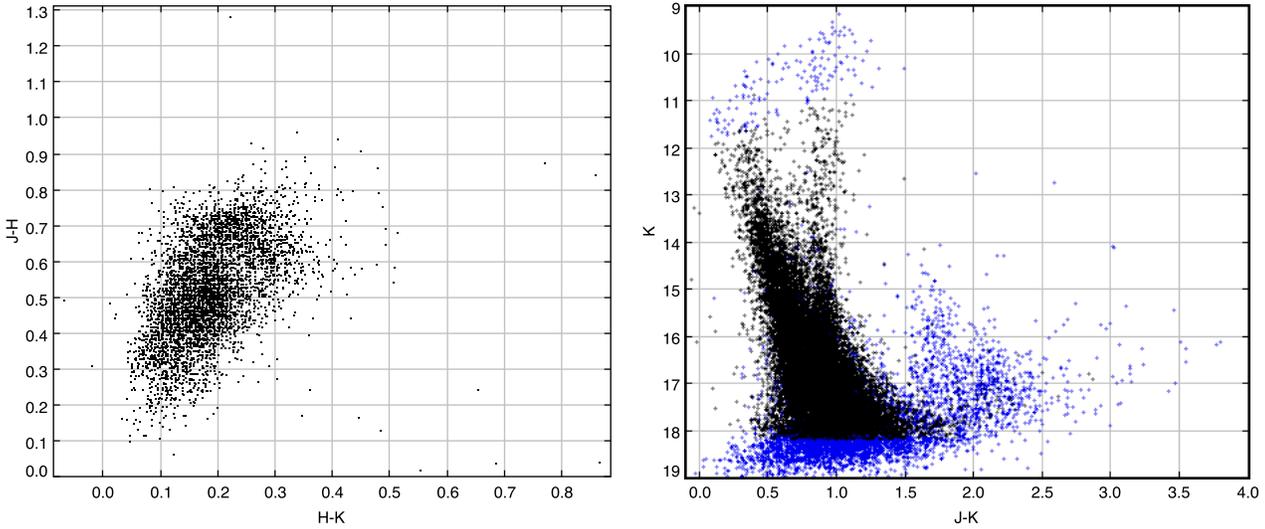

Figure 13. (l, b)=(173.65,0.65). The colour magnitude diagram for this field shows some similarity to figure 12, but exhibits greater extinction due to the location near the mid-plane. The principal sequences observed remain F and G dwarfs at the left of the diagram and late K and M dwarfs slightly to the right (mixed with red clump giants at $m_K \lesssim 14$). The population of external galaxies is prominent at $(J-K)$=1.5 to 2.5, $m_K > 15$. The two colour diagram appears different to that in figure 12 because there is sufficient extinction to redden the relatively distant population of F and G dwarfs and move them close to the location of the nearer, less reddened, late K and early M dwarfs. This creates a poorly defined mass of stars in which different spectral types are poorly distinguished. The points plotted are selected in the same way as in figure 2.
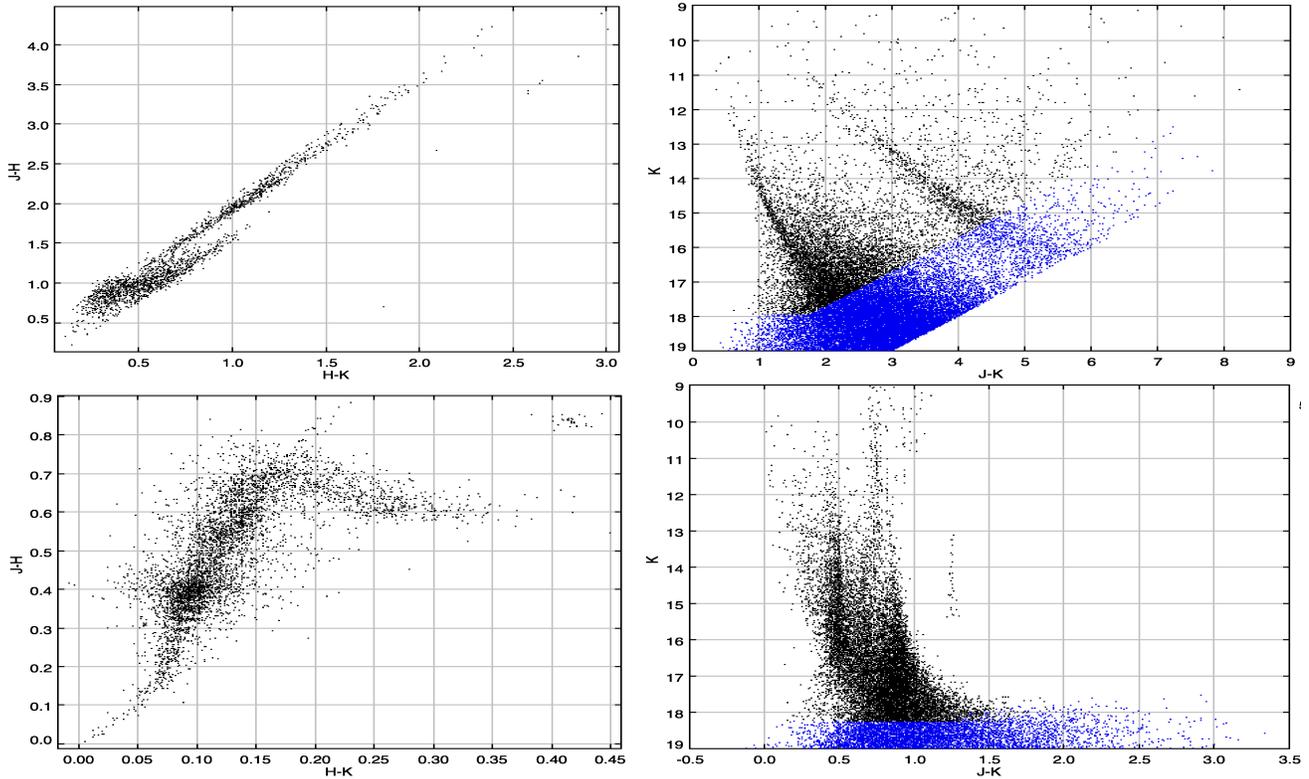

Figure 14. Besançon model results with synthetic errors. Upper panels: (l, b)=(31,0). Lower panels (l, b)=(171.1,4.75). These models reproduce the data fairly well, although our use of synthetic errors based on the archival values has underestimated the true errors at bright magnitudes (see §A2), causing the various stellar sequences to appear narrower than in the real data. The small, well defined sequence of rather red white dwarfs with $m_K \sim 14$ in the plots for (l, b)=(171.1,4.75) is not observed in figure 12 (see text §3.3). The A type stars near the origin in the lower left panel are not measured by the GPS because they are saturated. Points with synthetic errors >0.2 mag are plotted in blue.
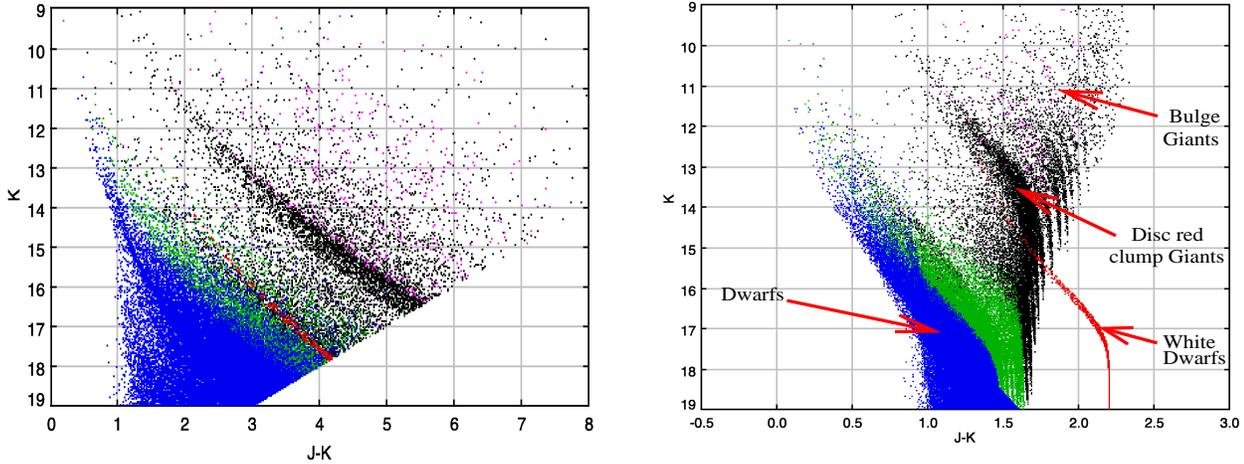

Figure 15. Besançon model K vs.*(J-K)* diagrams with no errors. Main sequence stars are shown in blue, luminosity class III giants are shown in black, subgiants (class IV) are shown in green, white dwarfs are shown in red and luminous giants (classes I and II) are shown in pink. Left panel: $(l, b)=(31,0)$, showing a fairly simple division between dwarfs and subgiants on the left and the red clump giant branch to the right. Right panel: $(l, b)=(15,1)$, showing the numerous sub-sequences of giant stars which comprise the red giant clump giant branch. The sequence of white dwarfs at the lower right is not observed.

magnitude function of Class III giants, with absolute magnitude M_K=-1.65 (e.g. Lopez-Corredoira et al.2002), though we caution that both flux and colour have some dependence on metallicity and age (Salaris & Girardi 2002; Luck et al.2007; Gullieuszik et al.2007). These giants form the well defined "red clump" in H-R diagrams for globular clusters and galaxies toward which the extinction is fairly uniform. They are therefore a useful tracer of stellar distance, extinction and population density, (see Lopez-Corredoira et al.2002) but only in fields in which they can be distinguished from dwarfs and other types of giant.

The dwarf and giant sequences do not always show a smooth increase in reddening with distance. The giant sequences in the (l, b)=(55,1) and (55,0) fields (see figures 8 and 7) show an abrupt increase in reddening between m_K=13 and m_K=14. Such features can be explained by discrete clouds of interstellar dust. A similar feature occurs in the (l, b)=(15,0) field (figure 3), where there is a sudden increase in reddening at m_K=12.75, *(J-K)*=2.25. The distance to the cloud and the extinction in front of it and within it can be simply determined from the known luminosity and colour of the red clump giants and by adopting an extinction law that is appropriate for the diffuse interstellar medium (e.g. Rieke & Lebofsky 1985; Cardelli, Clayton & Mathis 1989). (Here we neglect the effect of the change in effective bandpasses at high extinction that were mentioned above). In the case of the field at (l, b)=(55,1) the cloud is located at a heliocentric distance of 8 kpc and it introduces a visual extinction of A_V=7.5 magnitudes. Since the feature at m_K=13-14 is well populated with red clump giants it is likely to be caused by a large cloud of atomic gas rather than a relatively small dense molecular cloud. Inspection of the ^{13}CO data cube from the BU-FCRAO survey (see e.g. Shah et al.2004) shows weak but uniform emission across the field, with much brighter emission outside the field on both sides. The emission is too weak by more than an order of magnitude to explain the infrared extinction, which tends to support the interpretation of the cloud as an atomic feature rather than a molecular one.

An advantage of the near infared determination of extinction (as opposed to optical determinations) is that a "universal" extinction law applies to both the diffuse interstellar medium and molecular clouds (Cardelli et al.1989). This is due to the fact that the dust grains responsible for extinction have a size much smaller than the wavelength of observation for wavelengths $\lambda \gtrsim 1$ μm (except in extreme environments such as the accretion discs around protostars). Small variations in the extinction law can still occur, e.g. due to variations in grain composition (and hence refractive index). This may explain why some authors have found values of the colour excess ratio E(J-H)/E(H-K) ranging from 1.32 to 2.08 in some dark clouds (e.g. Moore et al.2005; Racca, Gómez & Kenyon 2002), bracketing the value of 1.70 found in Rieke & Lebofsky (1985). However, most measurements, e.g. Naoi et al.(2006) find that E(J-H)/E(H-K) lies in the range 1.6 to 1.7, and they note that some of the reported variations are attributable to differences in photometric systems.

Some of the colour magnitude diagrams show an abrupt change in the slope of the giant branch for another reason. For example, the plots in figures 4 and 9 for (l, b)=(15,1) and (98.4,0) show diagonal sequences of red clump giants at $m_K < 12$ and $m_K < 13$ respectively, and then a change to an almost vertical giant sequence at fainter magnitudes. This change is due to the red clump giant population leaving the main body of the Galactic disk at large distances. The position of stars along the red clump giant sequence is determined mainly by distance. At heliocentric distances $d >12$ kpc, the sequence in the (l, b)=(15,1) plot rises far enough above the dusty Galactic Plane for extinction to become almost independent of distance. The similar behaviour of the (l, b)=(98.4,0) plot is attributed to the northern Galactic warp, which moves the dusty plane away from b=0 at large Galactocentric radii. In figure 15 we show a Besançon model for (l, b)=(15,1) which reproduces and clarifies the behaviour at $d >12$ kpc. We see that the red clump giants are split into a number of faint parallel sub-sequences. These correspond to the various evolutionary groups: core

helium burning horizontal branch giants, fainter hydrogen shell burning stars ascending the red giant branch and asymptotic giant branch stars with hydrogen and helium shell burning (e.g. Robin 1989). Each evolutionary group is also split into multiple sequences due to binning by spectral sub-type in the Besançon model. Each sequence has a slightly different effective temperature and some, e.g. the K type red giant branch sequences, have lower luminosities. At $d > 12$ kpc the sub-sequences continue to become slightly redder at fainter magnitudes (i.e. larger distances) since there is a small amount of dust above the Galactic plane. However the sub-sequences all end ~ 2 magnitudes below the change in slope, as the old disc population declines to zero at large distances above the plane. At fainter magnitudes, new sub-sequences of slightly fainter giants with slightly bluer *(J-K)* colours (which we believe are stars ascending the red giant branch) come to dominate the giant branch. In the GPS data the adjacent sub-sequences merge together, with the result that in the vertical part of the giant sequence the stars become slightly bluer in *(J-K)* colour at fainter magnitudes.

The existence of less luminous hydrogen shell burning stars in the red clump indicates that the red clump method for determining distances, extinction and stellar population density should be used with caution at faint magnitudes. The Besançon model catalogue displayed in figure 15 for (l,b)=(15,1) indicates that at $m_K \gtrsim 15.5$ these less luminous giants dominate the red clump.

The field near the Galactic Centre at (l, b)=(-0.3,0) has a rather different colour magnitude diagram from the other fields. Three principal sequences are apparent in figure 2. The largest population is giants in the Galactic bulge, with $3 < (J\text{-}K) < 7$. According to the Besançon model these have a wide range of spectral types and metallicities. However most suffer similar reddening, since they are all at distances of 7-10 kpc (according to the model). The other populations are the nearby disc dwarfs at the left side of the diagram and the disc red clump giants, which form a diagonal sequence with *(J-K)* colours intermediate between the other two groups.

Moving to the outer Galactic fields, we consider first the diagrams in figure 12, for (l, b)=(171.1, 4.75). This shows a field with negligble reddening, which can be discerned from the corresponding two colour diagram. Two principal sequences of stars are apparent in the corresponding colour magnitude diagram, mostly with reliable photometry. A more diffuse clump of sources with "less reliable" photometry is situated near *(J-K)*≈1.8, m_K=17. This clump is composed of external galaxies (`mergedClass=+1, pstar`$\ll$ `0.9`), and the corresponding luminosity function increases down to the completeness limit (see §4.5). Inspection of the Besançon model catalogue for these coordinates (plotted in the lower panels of figure 14) indicates that the overwhelming majority of the sources in both of the two principal sequences are actually luminosity class V dwarfs. The left hand sequence is composed of F and G type dwarfs (and some subgiants of luminosity class IV). The right hand sequence is composed mainly of M and late K type dwarfs, with only a small proportion of giant stars. Luminosity class III giants are restricted to the upper portion of the right hand sequence with $m_K \lesssim 13.5$. The dwarf component of this sequence begins at $m_K \approx 12$ and extends down to the faintest sources at the bottom of the diagram. The overlapping dwarf

and giant populations in the right hand sequence are not distinguishable in the magnitude range $12 < m_K < 13.5$. The two colour diagram also fails to separate them, although it should in principle reveal any large population of early K-type red clump giants as an overdensity near *(J-H)*=0.57, *(H-K)*=0.12.

The reason that two sequences of dwarf stars are detected at (l, b)=(171.1, 4.75) is not immediately obvious. Inspection of the density map of the colour magnitude diagram shown in the lower panel of figure 12 (a "Hess diagram") and the Besançon model shows that there is a connection between the two sequences at $17 < m_K < 18$. However, the M type dwarfs, which are the most numerous population in the diagram, extend above and below this connection. Nearby late K and early M-type dwarfs have a narrow range of colours ((*J-K*)≈0.9) and they are sufficiently numerous to define the right hand dwarf branch at $12 < m_K < 17$. Similarly the distant F and early G-type dwarfs observed in this magnitude range also have a narrow range of colours. By contrast the late G and early K type dwarfs are spread over a wider range of *(J-K)* colours due to the steeper colour-temperature relation for these types. Their numbers are similar to the earlier type dwarfs in this magnitude range, so the rapid change in colour with temperature creates the sparsely populated gap between the two branches and the bimodal colour distribution. At $m_K > 17$ the late G and early K type dwarfs are sufficiently numerous to fill the gap.

The two sequences of dwarfs are present in all the colour magnitude diagrams plotted but they are less obvious at $l < 100°$. This is due to a combination of factors: (i) detectable F and G type dwarfs greatly outnumber M dwarfs near the mid-plane at $l < 100°$; (ii) there is a trend of increasing reddening with decreasing Galactic longitude, which causes the distant highly reddened F and G dwarf sequence to merge with K and M dwarf sequence; (iii) the population of distant red clump giants is much larger and produces a more obvious second sequence of stars to the right of the dwarf sequence that is clearly separated from the common F, G, K and M type dwarfs by high reddening. The K and M type dwarf branch is still detectable in some of the colour magnitude diagrams for l=98.4 and l=55 (see figures 8, 9, 10 and 11) appearing as a faint protuberance above the mass of dwarfs at $m_K \approx 14$.

The clump of external galaxies seen in the colour magnitude diagrams for the $l > 90°$ fields is not detected at smaller longitudes, owing to the combination of higher extinction through the plane and the reduced sensitivity caused by source confusion.

The two colour diagrams show clearly the trend of increasing extinction with decreasing Galactic longitude and latitude. The dependence on Galactic latitude is apparent even in the outer Galaxy, where extinction is relatively low. In the (l, b)=(171.1, 4.75) field (see figure 12) the densest cluster of sources near *(J-H)*=0.4 is composed of F and G type dwarfs. In the (l, b)=(173.65,0.65) field (see figure 13), we see that the F and G types have moved up to *(J-H)*=0.5, owing to the significant extinction present in the mid-plane toward these relatively distant sources (1 to 6 kpc). By contrast, the K and M type dwarfs with *(J-H)*=0.5 to 0.7 lie in the same place in both diagrams, owing to the much lower extinction toward these nearer and intrinsically fainter sources (<3 kpc distance). The effect of the northern

Galactic warp is apparent in the two colour diagrams for l=98.4. The extinction at (l,b)=(98.4,1) is similar to that at (l,b)=(98.4,0) and clearly greater than that at (l,b)=(98.4,-1), as shown in figures 9, 10 and 11.

3.3 Further comparison with the Besançon Models

The Besançon stellar population model has been used to aid the interpretation of the GPS data discussed above. In figures 14 and 15 we show some of the diagrams produced by the model in order to illustrate the quality and the limitations of such comparisons. The results in figure 14 have synthetic errors included in the simulation. The error curve used was based on a fit to the errors as a function of magnitude given in the WSA for each passband in the appropriate field. As noted in §A2, this will tend to underestimate the true errors (particularly for bright stars), but it is adequate for a simple comparison.

The visual extinction per kiloparsec in the diffuse interstellar medium (ISM) is a free parameter in the Besançon models. Discrete clouds may also be added to model strong extinction features, as noted earlier. The ISM extinction parameter was adjusted by trial and error until the best combined match by eye to the observed luminosity function and the K vs.*(J-K)* colour magnitude diagram was produced. The derived extinction was A_V=2.25 mag/kpc for the (l,b)=(31,0) simulation and A_V=0.7 mag/kpc for the $(l,b$=(171.1,4.75) simulation. The models use the extinction law of Mathis (1990), assuming R_V=3.1, so the equivalent K band extinctions are A_K=0.242 mag/kpc and A_K=0.075 mag/kpc. The default value of 0.7 mag/kpc is appropriate for the diffuse ISM and will usually be correct in fields with low extinction. Higher values are required to fit fields with high extinction. In reality high extinction is expected to be caused by numerous discrete molecular clouds, but often the individual clouds have too small an effect to be resolved in the data. We note that some authors quote a slightly higher value for the extinction in the diffuse ISM, e.g. Whittet (1990) quotes 0.8 mag/kpc. This difference is likely to be due to the choice of distance scale in the Besançon models, which places the Galactic centre at d=8.5 kpc from the sun. The distance to the supermassive black hole at the Galactic Centre has been reliably determined by matching the observed angular size of stellar orbits to the corresponding stellar radial velocities: d=7.62±0.32 kpc (Eisenhauer et al. 2005). Hence some users may prefer to scale the Besançon distances and extinction values accordingly.

The two colour diagrams in figure 14 for (l,b)=(31,0) and (171.1,4.75) are a good quantitative match to the data. The blue end of the model dwarf sequence for (l,b)=(171.1,4.75) appears sharper than the observed sequence in figure 12, since the photometric errors of these hot and bright stars are underestimated in the model. The other noticeable discrepancies in the (171.1,4.75) plot are: (i) the appearance of a cluster of sources at the upper right of the diagram (*(H-K)*=0.45, *(J-H)*=0.85), which is not observed; and (ii) the sparesely populated sequence of stars extending off the top of the diagram at *(H-K)*=0.2-0.25. The first group represents K type white dwarf stars in the model, which all have very similar masses and spectral types. The data suggests that the real white dwarf population has less uniform

parameters than in the model. The second group represents late K-type giants in the model. These are not included in figure 12 because they are too bright (i.e. heavily saturated sources). The two colour diagram for the (l,b)=(31,0) model shows a similar small population of luminous giants at *(H-K)*=2.5-3.0 (late M-types in that case) that is not seen in figure 5 for the same reason. Such bright populations are better studied with the 2MASS or DENIS surveys.

The colour magnitude diagram for the (l,b)=(31,0) model is in close agreement with the data in figure 5. The only difference is that slope of the red clump giant sequence at the upper right is more constant in the model than in reality. This reflects the patchy nature of interstellar extinction. The colour magnitude diagram for the (l,b)=(171.1,4.75) model is also in fair agreement with the corresponding data in figure 12. The following differences are obvious however. (1) The external galaxies at the bottom right of the plot in figure 12 are not in the Besançon model. (2) The two sequences of dwarf stars discussed earlier appear as three sequences at $0.45 < $ *(J-K)* < 0.9 in the model. The sparsely populated middle sequence at *(J-K)*=0.65 corresponds to early K dwarfs in the model. This may well be a real feature but it is not apparent in figure 12 due to the larger photometric errors in the real data. (3) The short vertical sequence of red sources at *(J-K)*=1.25 seen in the model are the K-type white dwarfs; these are not seen in the data, as noted earlier.

In figure 15 we show Besançon synthetic colour magnitude diagrams with no errors added, for (l,b)=(31,0) and (15,1). These illustrate the discrete binning of sources in the Besançon model grid. The synthetic plots for (l,b)=(31,0) appear very similar in figures 14 and 15 since distance and interstellar reddening introduce numerous degeneracies in magnitude and colour between different spectral types. In contrast, the plot for (l,b)=(15,1) clearly shows the numerous red clump giant sub-sequences (see discussion in §3.2). These appear well defined in the model because each subtype of giant star has a unique luminosity, effective temperature and colour in the model and there is no additional extinction to merge the sub-sequences in the dust free region above the Galactic plane. Some of the numerous subsequences correspond to the various evolutionary stages on the HR diagram, as noted earlier. In addition, the effect of binning by spectral sub-type in the model creates an artificial division which further multiplies the number of subsequences. We note that the more luminous giants above the most populated part of the red giant clump appear to be more numerous in the data than the model.

4 DEMONSTRATION SCIENCE

4.1 Identification of Young Stellar Objects with the UKIDSS GPS and the *Spitzer* GLIMPSE survey

One of the principal science goals of the GPS is to detect and characterise large numbers of star formation regions, in order to examine the effect of environment on star formation. Young Stellar Objects (YSOs) can be identified and classified by the excess emission from hot dust around the central protostar at wavelengths $\lambda \gtrsim 2\ \mu$m. The GPS can detect this
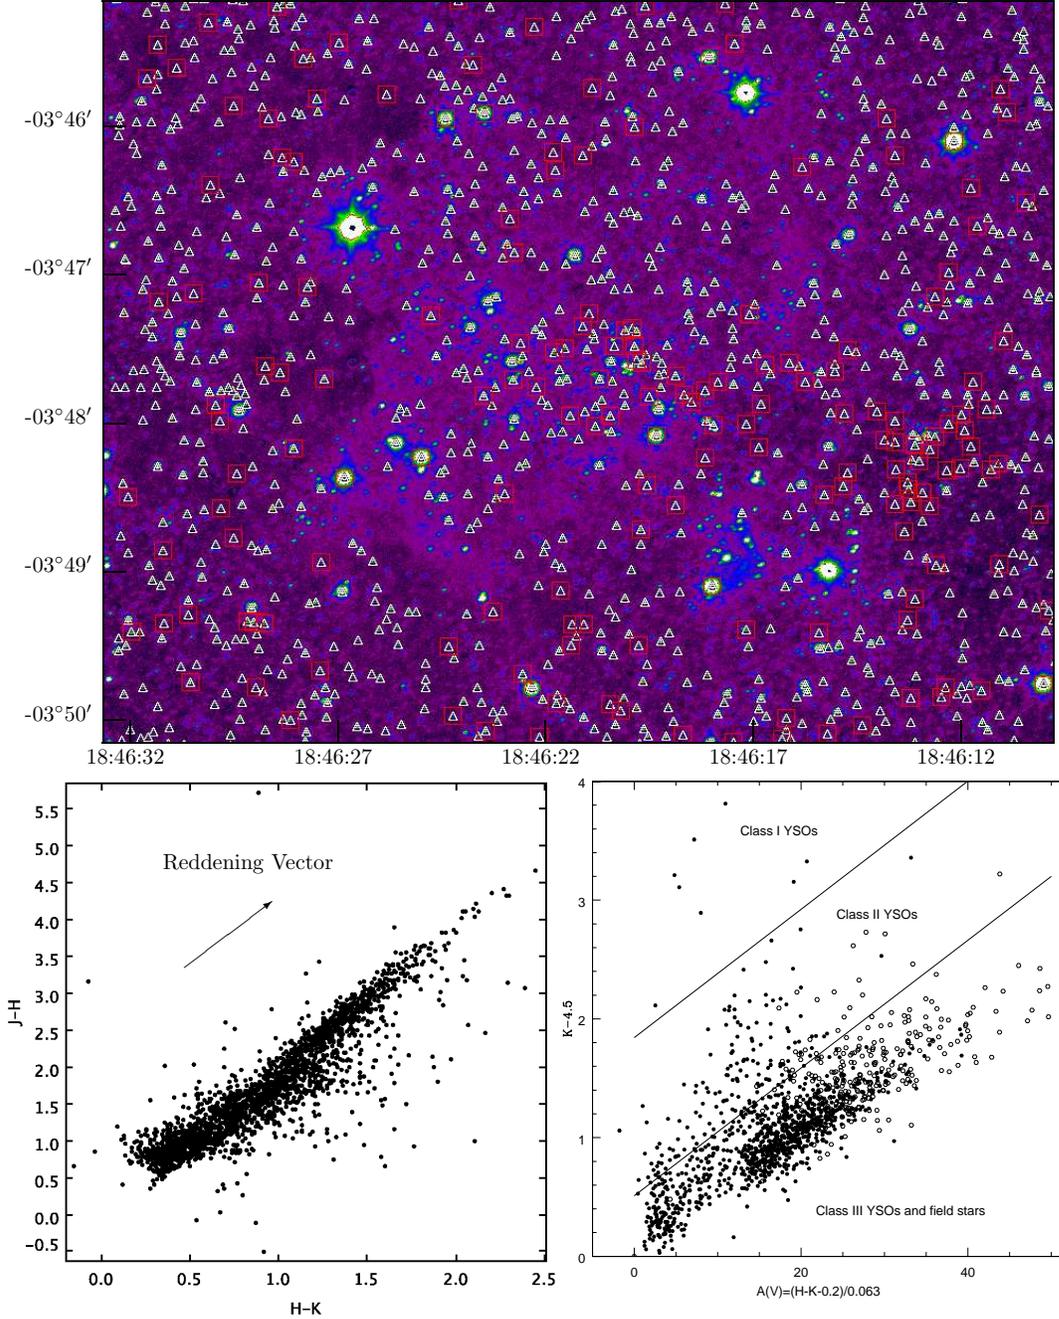

Figure 16. The synergy of UKIDSS-GPS and *Spitzer*-GLIMPSE data. (*top*) K band image of the central parts of a star formation region in the mid-plane: G28.983-0.603. Sources detected by GLIMPSE at both 3.6 and 4.5 μm are marked with white triangles. A 0.5 arcsec matching radius was used. Sources identified as Class I or Class II YSOs in the lower right panel are also marked with red squares in the image. The YSOs show a slight concentration towards the centre of the cluster. The lower panels show how the combination of near IR data from the GPS with mid-IR data from the *Spitzer* GLIMPSE legacy survey can be used to efficiently identify and classify YSOs by their K-4.5 μm excesses. JHK detections are plotted as filled circles in the lower right panel, while sources undetected in the J band are plotted as open circles. The near infrared reddening vector of Rieke & Lebofsky (1985) is plotted in the lower left panel. The lines in the lower right panel that divide the YSO classes are parallel to the reddening vector of Flaherty et al.(2007).

excess in some YSOs by using the *(J-H)* vs.*(H-K)* two colour diagram. However, the excess is larger and therefore more easily measured at mid-IR wavelengths. Mid-IR data from the *Spitzer Space Telescope* alone can be used to identify and classify YSOs (e.g. Whitney et al.2004; Churchwell et al.2004; Allen et al.2004; Megeath et al.2004). However, this requires a detection in three or four *Spitzer*-IRAC passbands and the relatively poor sensitivity and spatial resolution of the longer wavelength passbands at 5.8 and 8.0 μm limits the number of YSOs that can be classified. There is there-

fore a natural synergy between the GPS and the mid-IR *Spitzer* GLIMPSE legacy survey of the mid-plane (Benjamin et al.2003), particularly since the 2MASS survey generally has insufficient depth to adequately match GLIMPSE in star formation regions.

This is illustrated in figure 16 for the young cluster G28.983-0.603, which is coincident with an HII region observed by Lockman (1989). This cluster was identified by Bica et al.(2003) using 2MASS data and is listed as cluster 10 in their catalogue. A fair number of YSOs are identified via their K band excesses in the near IR two colour diagram (lower left panel), lying to the right of the principal sequence of reddened field stars and the more evolved "discless" Class III YSOs. However, the median *(H-K)* colour excess of YSOs is only $\sim$ 0.2 magnitudes (e.g. Wilking, Greene & Meyer 1999), so it is hard to distinguish cluster members with modest K band excesses from field stars. The lower right hand panel shows that the YSOs are far more clearly identified by using the (K-4.5) colour (many showing excesses >0.5 magnitudes) where the 4.5 μm flux comes from *Spitzer*/IRAC band 2. The horizontal axis in the lower right panel gives the approximate visual extinction, estimated from the *(H-K)* colour. In the lower right panel we plot the 1345 sources within a 6×6 arcminute box centred on the cluster that are detected in all of the J, H, K, 3.6 and 4.5 μm bands as filled circles. Sources which lack a J band detection are plotted as open circles. A 0.5 arcsec matching radius was used to combine the GPS and GLIMPSE data, since the default IPAC matching radius of 1.2 arcsec was found to create numerous false matches in this crowded field. We note that there are only 128 four band *Spitzer*-IRAC detections in this field, so the near IR/mid-IR combination increases the sample size by an order of magnitude. There is also an order of magnitude increase in the sample size for the YSOs.

The sources in the lower right panel of figure 16 are divided into Class I YSOs, Class II YSOs and Class III/field stars according to their K-4.5 μm excess by straight lines that are parallel to the reddening vector. The Class III/field stars form a continuous sequence parallel to the reddening vector but show an abrupt increase in the source density at $A_V \gtrsim 12$. Sources with a (K-4.5) excess are also located mostly at $A_V \gtrsim 12$ (typically at $12 \lesssim A_V \lesssim 30$) so we can infer that the cluster lies behind 12 magnitudes of visual extinction and that there is significant extinction within the cluster. Thus the near IR data allow us to identify stars with $A_V \gtrsim 12$ as the most likely cluster members. Lockman (1989) measured a radial velocity of 52.6±1.3 km/s for the HII region. Adopting a Galactic rotation model with a rotation speed of 220 km/s and 7.62 kpc as the distance to the Galactic centre (Eisenhauer et al.2005) we derive a kinematic distance of 3.1 kpc or 10.2 kpc. Inspection of the K vs. *(J-K)* colour magnitude diagram for stars in the same WFCAM field indicates a preference for the closer distance. This is because of stars in the red giant branch with $A_V{\approx}12$ have m_K=12-14, corresponding to distances of 2.9-7.3 kpc. The large spread is due to highly variable extinction across the field. The cluster lies in a extensive region of high extinction oriented east-west across the field, so $m_K{\approx}12$ and d$\sim$3 kpc is a reasonable distance to derive using the red giant branch and this is consistent with the nearer kinematic distance. The GPS data are fully complete to $m_K{\approx}16.0$ in this crowded field and are $\sim$50% complete to m_K=17.25.

At d=3.1 kpc, m_K=17.25 corresponds to very low mass pre-main sequence stars with masses as low as M$\sim$0.095 M$_\odot$ (using the NextGen isochrone of Baraffe et al.1998 for an age of 1 Myr) in the absence of extinction. Such sources would be detected if they were ejected from the region of high extinction in which most of the cluster lies. For cluster members with a more typical extinction of A_V=21 (A_K=2.35), the 50% completeness limit corresponds to low mass stars with M$\sim$0.5 M$_\odot$.

The locations of the dividing lines were determined using information from Gutermuth (2005) in which Class I, Class II and Class III YSOs (with classifications determined from 4 band IRAC detections) were plotted in the dereddened (K-3.6) vs. (3.6-4.5) two colour diagram. Gutermuth (2005) found that the different YSO classes were easily located in that diagram since the colours correlated excellently with the colours in the (3.6-4.5) vs.(5.8-8.0) IRAC two colour diagram. The near IR and mid-IR passbands with the best sensitivity to reddened young stars are H, K, 3.6 μm and 4.5 μm. Gutermuth (2005) therefore devised a sophisticated scheme to classify the numerous YSOs detected in only these 4 passbands. To briefly summarise the method, he dereddened sources with J band detections to the classical T Tauri locus of Meyer, Calvet & Hillenbrand in the *(H-K)* vs. *(J-H)* diagram and thereby determined the individual extinction values. He used that information to plot YSOs in a dereddened *(H-K)* vs. (3.6-4.5) two colour diagram and find the the best fit locus of YSO colours. The larger sample of sources which lack J band detections were then dereddened to this locus in the observed *(H-K)* vs. (3.6-4.5) diagram, taking advantage of the fact that the locus is inclined to the reddening vector by a large angle in that diagram. Finally, he used the extinction values for the full sample to classify YSO candidates using their location in the dereddened (K-3.6) vs. (3.6-4.5) diagram. This diagram was found to be the best diagram for clasifying YSOs, owing to the significant infrared excesses of protostars on both axes.

In the lower right panel of figure 16 we have used a scheme which is simpler in some ways but is more effective in crowded GPS/GLIMPSE fields. We find that the dereddened (K-3.6) vs. (3.6-4.5) diagram does not readily detect the YSOs in this field due to the far larger number of field stars and the large uncertainties in the 3.6 and 4.5 μm fluxes, which cause many stars to scatter into the region occupied by YSOs. These large uncertainties are due to the fact that the GLIMPSE legacy survey is shallower than most *Spitzer* GO observing programmes: it was designed to provide quite literally a glimpse of a very large area of the Galactic plane. In comparison the GO programmes also usually have fewer field stars contaminating the sample since the nearby star formation regions in the Gould belt often lie off the Galactic plane. We use a simpler formula for extinction: $(A_V = (H - K - 0.2)/0.063)$, which is based on the extinction law of Rieke & Lebofsky (1985), with *(H-K)*=0.2 adopted as the typical intrinsic colour of most stars. This formula does not take account of the fact that YSOs will have an *(H-K)* excess due to hot circumstellar dust. However, by avoiding use of the GLIMPSE fluxes in calculating extinction we greatly reduce the scatter in the lower right panel of figure 16. Like Gutermuth, we use the extinction law of Flaherty et al.(2007) to determine the extinction in the mid-IR bandpasses, relative to the K band. Flaherty et

al.(2007) report a possible difference in the extinction law for dark clouds and for the interstellar medium, the latter being calculated by reanalysing the data of Indebetouw et al.(2005). The difference could increase the gradient of the dividing lines in the lower right panel of figure 16 by 5%, leading to a different classification for a small number of sources. We note that the common method of dereddening to the Classical T Tauri star (CTTS) locus of Meyer et al.(1997) runs into difficulties in GPS datasets containing a variety of dwarf and giant field stars that do not lie on the locus. In any case, the CTTS locus requires fluxes in the J bandpass, which are often unavailable.

We therefore recommend the use of diagrams similar to the lower right panel of figure 16 for simple classification of YSO candidates in GPS data. The extinction axis helps to identify stars that are likely to lie in front of or behind the cluster and the $(K$-4.5$)$ colour contains most of the information in the dereddened $(K$-3.6$)$ vs. $(3.6$-4.5$)$ diagram. The use of the $(H$-$K)$ colour to determine extinction will lead to a systematic overestimate of the extinction towards YSOs, but a typical $(H$-$K)$ excess of 0.2 magnitudes will lead an overestimate of only 3 magnitudes in the extinction, which is small in the context of figure 16. After the likely YSOs have been identified this bias can be allowed for.

We caution that there are limits outside which these YSO clasifications become unreliable. Gutermuth (2005 and private comm.) noted that his classification system was calibrated using low mass protostars. It is not calibrated for more massive YSOs (Herbig Ae/Be stars) or for proto-brown dwarfs, which the Class I/II/III system of Lada et al.(1984) was not designed for. Herbig Ae/Be stars are likely to be the most numerous types of YSO detected in distant GPS clusters so further work will be needed to devise a classification scheme for them.

## 4.2   GPS data in nebulous star formation regions: M17

The well known high mass star formation region M17 was included in the UKIDSS Science Verification programme undertaken in April-May 2005, before the start of survey operations. A single WFCAM tile was observed in the three near IR passbands, using the same total exposure times as the GPS. The central portion of the K band image is shown in figure 18. It was noted in Lawrence et al.(2007) (see also §A2) that the WSA fails to include almost all the stars that are apparent in the regions of brightest nebulosity. This is due to a limitation of the source detection algorithm in the CASU reduction pipeline that is planned to be fixed from DR5 onward. Here we show the results of our own crowded field profile fitting photometry of the images from the WSA with IRAF/DAOPHOT and a comparison with the published data of Jiang et al.(2002), which covered a much smaller part of the same field. Only the central 4 arrays out of the 16 in the WFCAM tile contain bright nebulosity, and then only in a minority of each array. We used a 5σ threshold for the source detection with DAOFIND for each array in each filter. Visual inspection showed that this produced very few spurious detections. Image profiles were generated using ∼15 isolated stars in each array, assuming a spatially independent profile. The photometry was calibrated by comparison with the WSA catalogue for each array, using the

median zero point correction for the sources common to both catalgoues. Finally, the photometry for these four arrays was band merged in TOPCAT with a 0.5 arcsec pair matching radius and then merged with the WSA catalogue for the other 12 arrays in the tile. A total of 788841 sources were detected in the GPS field.

In figure 17(a-b) we show the linear and cumulative K-band luminosity functions (LFs) of regions 1C, 1N, 1S and 2C defined by Jiang et al. (2002) (these are illustrated in the right hand panel of figure 18.) While the overall LFs exhibit similar characteristics to those in figure 7 of Jiang et al., figure 17(c) shows quantitatively to what extent both sets of LFs are in agreement. In general, the WFCAM-derived LFs contain more objects at fainter K-band magnitudes than those of Jiang et al., and reach a similar limiting magnitude. The number of sources detected in each region in the GPS data is (1047, 7402, 3658 and 1711) for (1C, 1N, 1S and 2C) respectively. This compares with figures of (528, 2584, 1588 and 1367) for the same regions in Jiang et al.(2002). The excess of objects in our LFs is most likely due to the superior spatial resolution of UKIRT, relative to the set up used by Jiang et al. Our WFCAM observations are characterised by about 0.8 arcsec FWHM and have 0.2 arcsec pixel sampling after microstepping. This compares very favourably with the 0.45 arcsec pixels of the SIRIUS camera on the Infrared Survey Facility used by Jiang et al., which is located at a site in South Africa with a typical seeing of 1.5 arcsec FWHM. This is supported by figure 17(c): region 1C exhibits the highest stellar density, and shows a systematically greater number of objects in our LFs compared to those of Jiang et al., for $K \gtrsim 12$ mag down to the detection limit of both sets of observations. Regions 1N and 1S, coinciding with the northern and southern nebular regions near the core of M17, also have fairly high-density subregions. As such the excess of fainter sources ($K \gtrsim 14$ mag) compared to Jiang et al. – in particular in region 1N – is not surprising if we assume that the difference in spatial resolution is the driving force behind this behaviour.

An effect of the larger number of detections in the UKIDSS data is to shift the peak of the LFs in the crowded regions 1C and 1S to fainter magnitudes than in Jiang et al.(2002). In that publication the authors were unsure whether the different locations of the peaks in the different regions were due to an actual property of the regions or to issues of depth and spatial resolution. It now seems clear that the differences are caused by spatial resolution effects, and still deeper observations with even higher resolution will be required to search for any genuine differences.

In figure 18 we show an extinction map of the region. This was generated by calculating the extinction towards each individual star and averaging the results in 15 arcsecond bins, then gaussian smoothing the results with a FWHM of 1.5 bins. The region of high extinction clearly follows the "Omega" shape of M17 (also known as the Omega Nebula). In regions of very high extinction the extinction derived by this method is low, evinced by the white regions with the darkest parts of the map. This is because the densest part of the molecular cloud obscures all the background stars that dominate the star counts in most other parts of the map, so only foreground stars with low extinction are detected. The extinction towards individual stars was derived from the measured H and K fluxes using the simple formula A_V=(H-
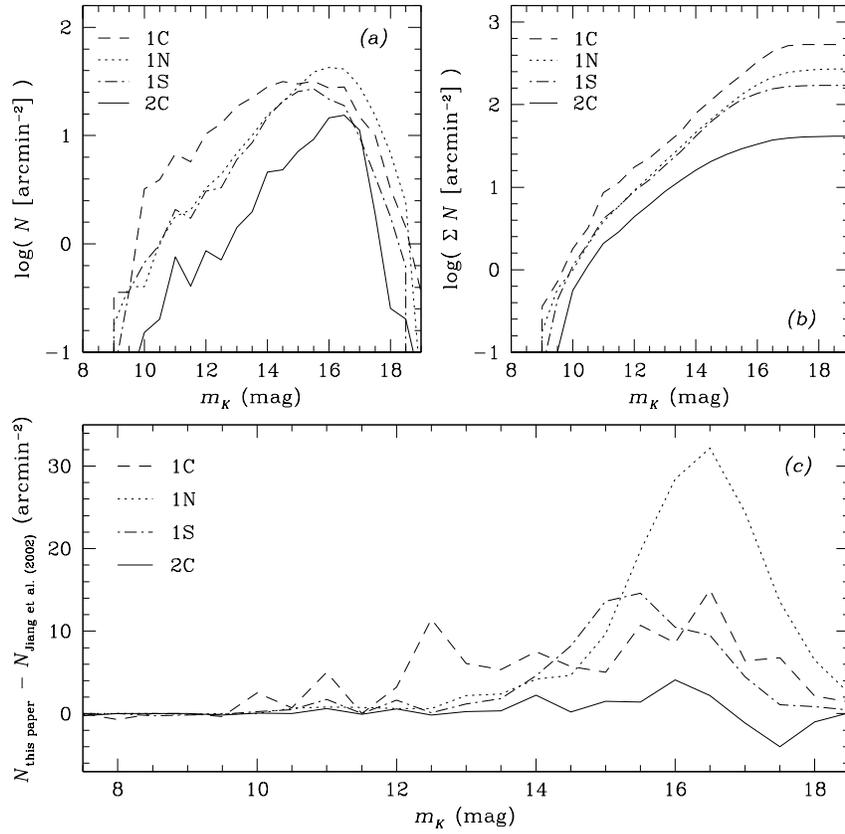

Figure 17. K band Luminosity Functions for M17 in the regions "1C", "1N", "1S" and 2C defined by Jiang et al.(2002). The top left panel shows the LFs, the top right panel shows the cumulative source counts and the bottom panel compares the source density with that measured in the same regions by Jiang et al.(2002).
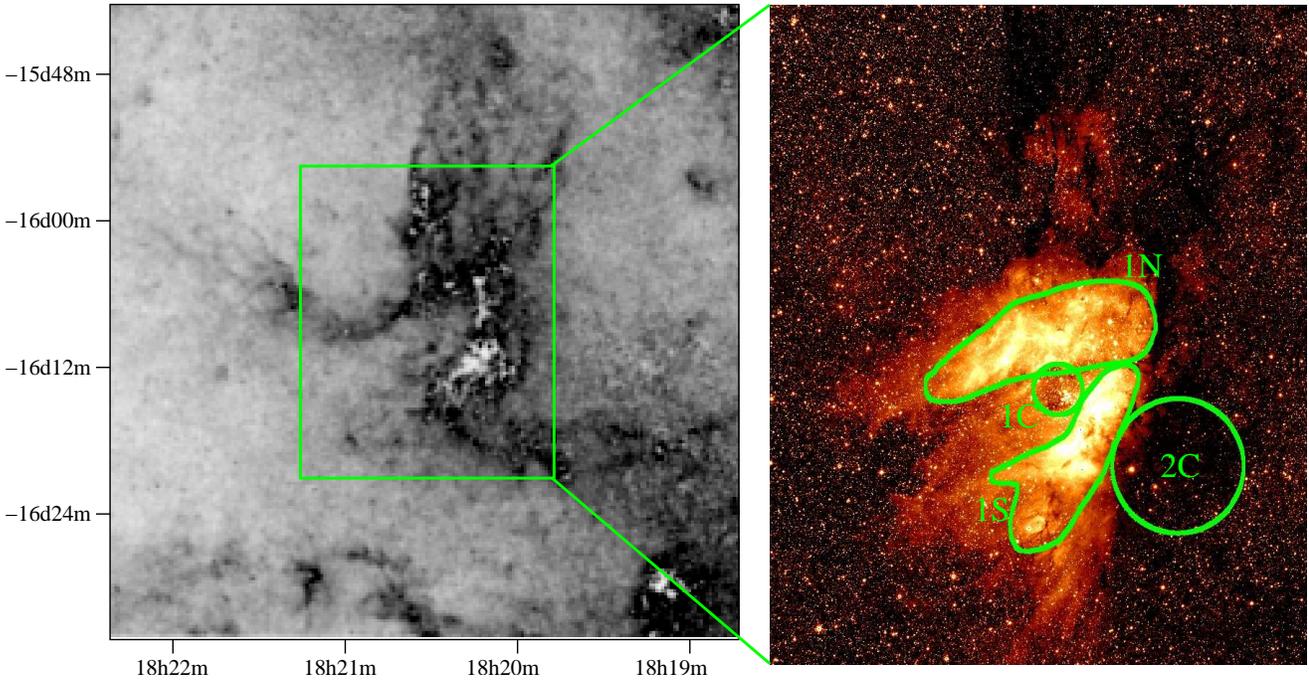

Figure 18. *(left)* Extinction map of the M17 field, illustrating the "Omega" shape of the nebula. The greyscale runs from $A_V=0$ (white) to $A_V=26$ (black). The extinction for each star was derived from the *(H-K)* colour and the results were averaged in 15 arcsecond bins (see text §4.2). The white regions surrounded by black are places with very high extinction where only foreground stars are detected. *(right)* K band image of the central portion of the field, illustrating the location of the regions used in figure 17.
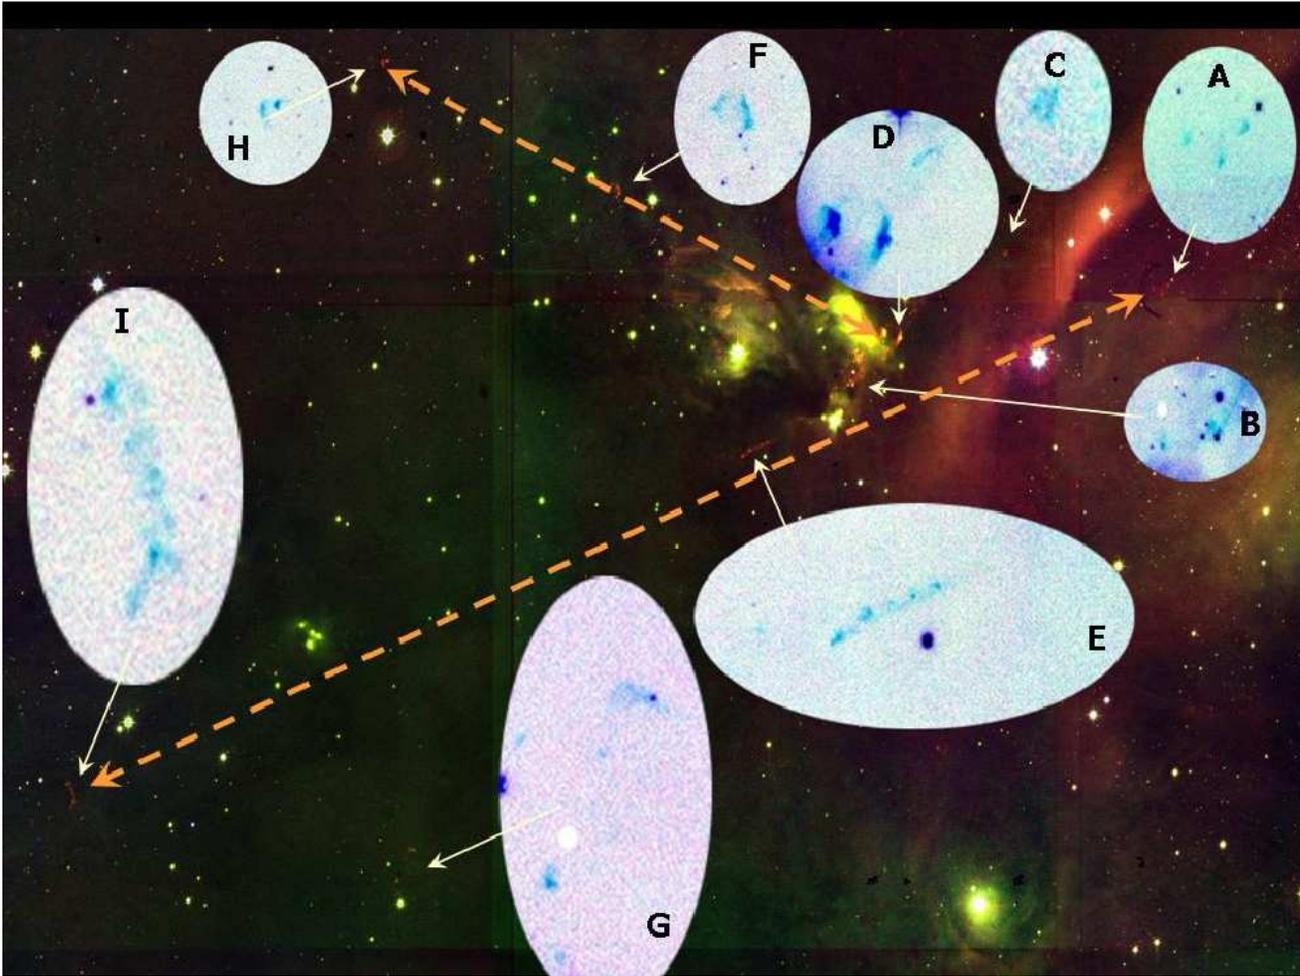

Figure 19. A three colour JKH$_2$ image centred on the L1688 dark cloud in ρ Ophiuchi. Red patches show H$_2$ emission where the outflows impact the denser environment, creating compressed layers of shocked emission revealed in the 2.12 μm filter. Blue and green colours correspond to emission in the J and K bands respectively. The image size is 31$'$ 40$''$ × 18$'$ 44$''$. The insert images show close-ups of several of the H$_2$ shocks (2.12 μm images with no continuum subtraction) with the following identifications from Gómez et al.(2003) (labelled G) and Khanzadyan et al.(2004) (labelled f). Insert A: New feature; B: G14; C: G8a; D: G11,G12,G13, HH313; E: G20, f10-04; F: G24, HH79a; G: G3, f09-01; H: G25, HH711; I: f08-01a

K-0.2)/0.063, as in §4.1. Comparison with the K band image in the right hand panel of figure 18 shows that the Ω shape of high extinction (i.e. the Giant Molecular Cloud) follows the outer rim of the HII region, which is ionised by the cluster located in region 1C. Regions with high extinction located further north and west of the HII region are seen as dark areas in the K band image.

A full analysis of the M17 data will be presented in a future paper.

4.3 H$_2$ emission in the ρ Ophiuchi dark cloud

Figure 19 shows results of WFCAM H$_2$ imaging of the ρ Ophiuchi dark cloud. These data were taken as part of UKIDSS GPS Science Verification in April 2005 with the same integration times as the TAP survey (see §2), covering a 52×52 arcminute field. The ρ Ophiuchi cloud has been the focus of many programmes to understand the formation of low-mass stars. While it is difficult to detect the youngest YSOs (Class 0 protostars) because their near IR radiation is obscured by the material from which they form, prodigious outflowing streams of molecules are often visible at near infrared wavelengths

The WFCAM data have uncovered a number of new parts of these flows. Whereas previous surveys attributed the driving sources to be within a few arcminutes, the wide field makes it possible to piece together outflows which may extend over 30 arcminutes corresponding to parsec scale flows. Two such outflows are indicated in figure 19. The data suggest that much of what we see spread out on the largest scale in ρ Ophiuchi is actually driven from a single active clump. One can then determine the true number of outflows and determine their full extent. With the aid of future epochs of observation it will be possible measure their velocity and
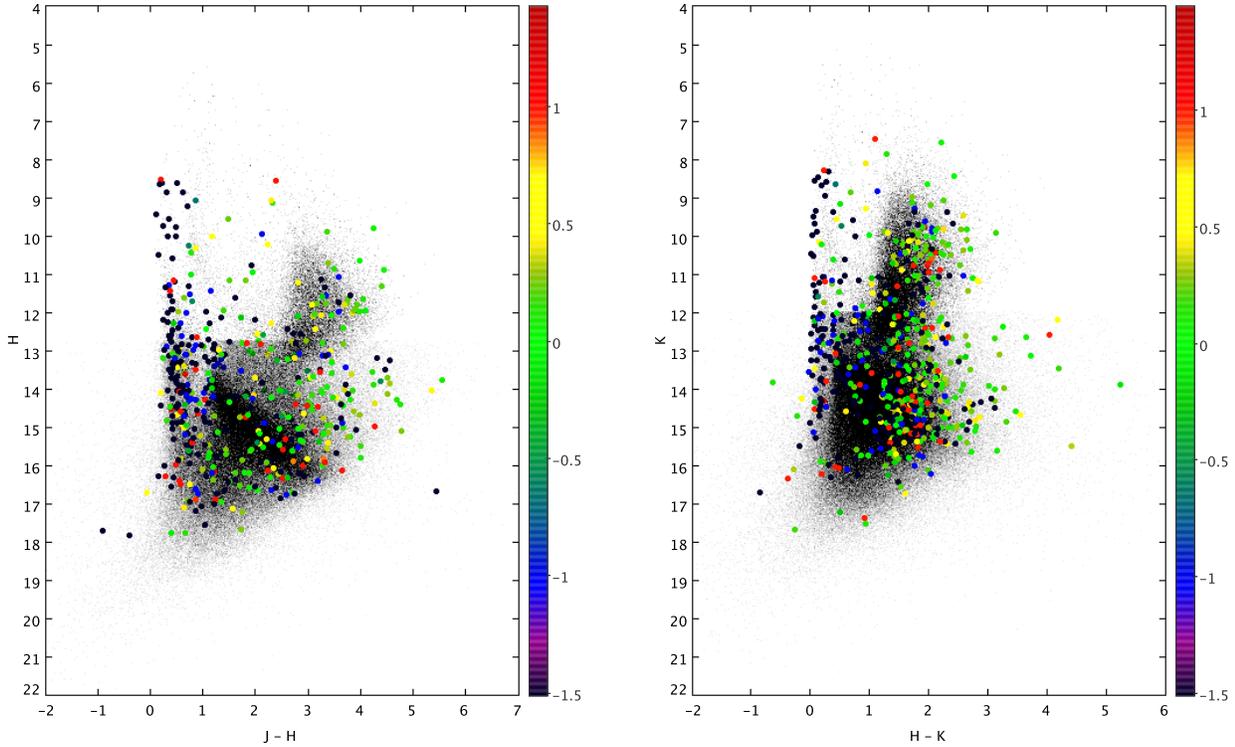

Figure 20. Colour magnitude diagrams (CMDs) of the candidate counterparts to the *Chandra* X-ray sources (*coloured* points) overlaid on a randomly selected sample of the Nuclear Bulge stellar population (small *black* points) from the UKIDSS DR2 and 2MASS (used for sources too bright for UKIDSS DR2 where saturation results in inaccurate photometry). All sources are selected from the $2° \times 0.8°$ region centred on Sgr A* of the *Chandra* Nuclear Bulge X-ray survey. It is clear that the candidate counterparts trace the overall stellar population. The CMD containing *J* band data has a higher proportion of local dwarf candidate counterparts, indicating this could be used to identify more local X-ray sources. The X-ray source candidate counterparts are coloured representing the *Chandra* hard colour (colour bars representing the colour association, see text §4.4 for details of *Chandra* hard colour) showing that the local dwarf candidate counterparts are more commonly associated with X-ray sources with low values of colour indicating soft spectra, low absorption or both. X-ray source counterparts plotted in in black have no net counts in one of the two energy bands (see Muno et al., 2006)

hence estimate their ages and calculate the feedback of mechanical energy into the cloud. Similar parsec scale flows associated with low mass star formation have been identified in several other nearby molecular clouds, (e.g. Bally & Devine 1994; Devine 1997).

In figure 19 the red patches mainly correspond to the locations where the outflows impact with the environment, creating compressed layers of shocked H_2 revealed by the 2.12 μm filter. Blue and green correspond to J band and K band respectively. Despite their large spatial extent, these flows have dynamical lifetimes that are only of order 10^4 years, assuming typical flow velocities of 100-200 km/s. Since the outflows appear to be driven from a single clump this suggests that only a few protostars are driving them. The fact that most of the pre-main sequence stars in the cloud do not seem to be generating detectable molecular outflows suggests that the active stage of protostellar accretion is extremely short, presumably of the same order as the dynamical timescale inferred from the extent of the jets detected in these data. This argument assumes that most or all protostars drive molecular jets when undergoing rapid accretion.

4.4   X-ray sources in the Nuclear Bulge

We have performed matching of the UKIDSS DR2 **gpsSource** catalogue to the ~4200 *Chandra* X-ray sources of the Muno et al.(2003; 2006) catalogues to search for the candidate counterparts to the X-ray sourcesdetected on sight lines in the vicinity of the Galactic centre. The X-ray data covers an approximately rectangular 1.6 deg^2 area at $-1<l<1$, $-0.4<b<0.4$. There are some gaps in the UKIDSS DR2 area coverage in this region, so the area of the cross match is 1.21 deg^2. The area contains 2.0×10^6 infrared sources with an average spatial separation of 2.8″. As shown in Bandyopadhyay et al.(2005), to identify candidate counterparts to X-ray sources in the Nuclear Bulge, very high resolutions are required to avoid issues of confusion due to the high stellar density. The UKIDSS survey is the first of its type to have sufficient resolution, depth and area coverage of the Nuclear Bulge for such a task to be undertaken. It has sufficient depth to detect giant stars of all types in the Nuclear Bulge as well as a significant fraction of all main sequence stars to A or F type. By contrast, the 2MASS survey detects only M giants and O-B type main sequence stars in the Nuclear Bulge (Cox 2000). Even more

X-ray error size (arcsec)	Number of candidate counterparts				
	1	2	3	≥ 4	Total
$0'' - 1''$	523	110	49	27	709
$1'' - 2''$	600	153	58	43	854
$2'' - 3''$	245	78	44	33	400
$0'' - 3''$	1368	341	151	103	1963

Table 1. The numbers of candidate counterparts to the Muno et al.(2006) catalogue of X-ray sources from the Wang et al.(2002) *Chandra* observation of the Nuclear Bulge. The number of counterparts has been broken down in to X-ray sources with positional errors of $0'' - 1''$, $1'' - 2''$, $2'' - 3''$ and the total numbers on the bottom row.

importantly, the spatial resolution of UKIDSS is adequate to identify the correct candidate counterpart to a large fraction of the X-ray sources, whereas the $2''$ resolution of 2MASS results in severe source confusion and a much greater likelihood of mis-matching.

Numerous studies have tried to characterise these newly discovered X-ray sources in the Bulge based on their X-ray properties. Pfahl et al.(2002) suggest that a large fraction may be wind-accreting neutron stars with high mass companions. Muno et al.(2003; 2006) and Ruiter et al.(2006) propose that they could be white dwarfs accreting from main sequence counterparts (cataclysmic variables, polars and intermediate polars). Willems & Kolb (2003) and Liu & Li (2006) believe them to be neutron stars with low mass companions and Wu et al.(2007) have speculated that they could be isolated neutron stars and black holes accreting from the interstellar medium. Without positive identification of the stellar counterparts to these X-ray sources we will not be able to differentiate between all these possibilities. The extremely high, variable extinction towards the Nuclear Bulge requires these observations to be performed in the infrared. As mentioned above, the UKIDSS GPS is the first infrared survey to have the resolution to allow the identification of candidate counterparts to the whole population of X-ray sources and so will be a vital tool in the understanding of this population.

We used TOPCAT to identify candidate counterparts to the X-ray sources. The stated positional accuracy of UKIDSS is $\sim 0.1''$ as matched to the 2MASS survey. We used a larger $0.3''$ positional error for the UKIDSS DR2 source positions to account for the possible confusion in the Nuclear Bulge caused by the very high stellar density. The "out-of-the-box" *Chandra* positional error is $1''$, though this can be considerably larger (up to $9''$) in some cases due to image distortion in the outer regions of the *Chandra* array and/or to the very low S/N of the faintest sources detected. For the purpose of this study, we discarded all X-ray sources for which the X-ray positional errors were greater than $3''$ radius; for error circles greater than this size, the number of candidate IR counterparts is sufficiently high (5-30 stars) to render meaningless any attempt at astrometric matching between the IR and X-ray catalogs. We used the $0.3''$ positional error for the UKIDSS DR2 source positions, along with the derived positional errors from the Muno et al.(2003; 2006) X-ray source catalogues to set a maximum separation of $3.3''$ between and X-ray source and a star that can be considered a match.

Of the 4256 X-ray sources in the Muno et al.(2003; 2006)

catalogues, 3963 X-ray sources have positional errors of less than $3''$. From these, we found 3076 candidate counterparts to 1963 of the X-ray sources. There are 1368 X-ray sources with only one candidate counterpart, 341 with two candidate counterparts, 151 with three and 103 with 4 or more candidate counterparts. Table 1 gives a breakdown of the numbers of counterparts for X-ray sources with error circles of $0'' - 1''$, $1'' - 2''$ and $2'' - 3''$. As can be seen, for X-ray sources with positional errors of $0'' - 1''$, the majority of these have only one candidate counterpart. Those with $1'' - 2''$ errors have a slightly larger proportion with 2 candidate counterparts. As might be expected, the sources with the larger error circles, $2'' - 3''$, have a much larger proportion with multiple candidate counterparts.

Figure 20 shows colour magnitude diagrams (CMDs) of the candidate counterparts compared to a representative sample of Nuclear Bulge stars from the UKIDSS DR2 catalogue. The plots include both UKIDSS data and 2MASS data, the latter being used at bright magnitudes where stars may be saturated in the UKIDSS GPS. The saturation limits in the GPS vary depending on the sky background and seeing. Conservatively it is best to assume that sources with $m_K < 12.0$, $m_H < 12.75$ or $m_J < 13.25$ may be saturated although the typical saturation limits are ~ 0.5 magnitudes brighter than this. The saturation limit for individual fields can be determined with the `ppErrbits` parameters in the WSA (see §A2) but here we used the above thresholds for simplicity.

From the diagrams it can be seen that the X-ray sources follow the general trend of the overall stellar distribution but with some differences to their specific distribution. In particular, the CMDs containing J band data reveal a disproportionately high proportion of the candidate counterparts to be in the local, main sequence arm of the CMDs (see §3.2 for discussion and analysis of the CMDs of the Bulge). The majority of the remaining candidate counterparts in all three CMDs are consistent with red giants at the distance of the Bulge with variable levels of extinction. Figure 20 also shows the X-ray source counterparts colour-coded by the X-ray hard colour taken from the *Chandra* catalogue (hard colour is defined as: $(h - s)/(h + s)$, where h and s are the net counts in the 4.7-8.0 keV and 3.3-4.7 keV energy bands; Muno et al., 2006). Sources detected only in one of these two bands are plotted in black. As is clearly visible, the colours show that the X-ray sources with local, dwarf candidate counterparts have a higher proportion of sources with low values of colour, indicating a soft spectrum and/or low absorption. The large proportion of single X-ray band

detections (black points) in the local dwarf branch is mainly due to sources detected only in the 4.7 keV band, which is consistent with these being mostly soft X-ray sources.

Based on the identification of candidate counterparts to these X-ray sources, we can draw some early conclusions as to the likely nature of the different populations of X-ray sources. We can separate the sources into those with local dwarf candidate counterparts and those with Bulge giants when analysing the populations. We noted above that the local dwarf candidate counterparts have a higher likelihood to be associated with X-ray sources with low values of hard colour, indicating either an intrinsically soft spectrum or low absorption. Since local dwarfs make up only a small fraction of the total number of sources in this Nuclear Bulge field, the fact that they are disproportionately represented among the candidate X-ray source counterparts indicates that these are almost certainly genuine matches, most likely CVs or X-ray active stars. For the X-ray sources with Nuclear Bulge giant counterparts, we see a generally higher value for the X-ray source colour indicating a harder or more absorbed X-ray spectrum in line with the higher level of absorption expected for the Nuclear Bulge X-ray source population. The very high stellar density (average separation of $2.8''$ in the GPS and $1.94''$ at $K = 19$; Gosling et al.2006) does mean that a fraction of the Bulge candidate counterparts will be chance positional coincidences, but the correlation of "hard" X-ray sources with Nuclear Bulge giant counterparts suggests that we are detecting true companions to many of the X-ray sources. The colour distribution of the candidate counterparts suggests the population to be predominantly Nuclear Bulge giants, an older, more evolved population. These systems make up the majority of the total population of X-ray sourcescounterparts. They are likely to be dominated by LMXBs with evolved companions.

4.5 External galaxies in the Zone of Avoidance

External galaxies located close to the Galactic plane are hidden from view at optical wavelengths by the high extinction. For this reason the Galactic plane is referred to as the "Zone of Avoidance" or "ZoA" in extragalactic studies. Locating relatively nearby galaxies (within ∼100 Mpc) in this region is of interest for studies of the structure and kinematics of the Local Group and as well as nearby large-scale structures. This includes revealing the nature of the "Great Attractor", e.g. Dressler et al.(1987); Kolatt et al.(1995); Kraan-Korteweg & Lahav 2000, Schröder et al.(2007); Kocevski et al.(2007); and the origin of the dipole in the Cosmic Microwave Background. Near infrared surveys such as 2MASS and DENIS have proved their effectiveness in penetrating the ZoA (Jarrett et al. 2000b; Rousseau et al. 2000) provided the star density does not exceed a certain value (Kraan-Korteweg & Jarrett 2005). The potential for such studies is greatly improved by the higher sensitivity and spatial resolution of the GPS. Furthermore, the star-galaxy separation is improved by the additional detection of the fainter galaxy disks.

We noted in §3.2 that external galaxies form a diffuse but well defined group of spatially resolved sources ($\mathtt{pstar} \ll 0.9$) at the lower right of the colour-magnitude diagrams for fields in the outer galaxy ($l > 90°$). The populations of external galaxies in figures 9 to 13 are located

at $1.5 < (J-K) < 3.0$, $m_K > 14$. The galaxies appear redder in figures 9 to 11 than in figures 12 to 13, owing to the greater extinction along the line of sight at $l=98°$ than near $l=170°$. We note that the vast majority of these galaxies are too faint to be detected in 2MASS.

In colour-magnitude diagrams for the outer galaxy that employ the (J-K) colour (see figures 9 to 13) there is very little overlap between the stars classified as having "more reliable" photometry and the spatially resolved extragalactic sources, which are included in our "less reliable' category (marked with blue points). The paucity of point sources in the extragalactic group demonstrates that WF-CAM has spatially resolved the great majority of galaxies that are detected in the GPS. Inspection of the parameters in **gpsSource** for the objects in the region of the plots occupied by the extragalactic group shows that nearly all of them have $\mathtt{pstar} \ll 0.9$, $\mathtt{pGalaxy} > 0.9$ and $\mathtt{mergedClass=+1}$. A significant fraction of the individual sources are not unambiguously resolved in a casual visual inspection of the image data, but the classification in the WSA clearly benefits from the quantitative measurement of the observed spatial profile in all three passbands that is provided by the reduction pipeline. In the WSA, the nature of the profile is described by the parameter $\mathtt{mergedClassStat}$, which describes the extent to which a source appear stellar, resolved, or undersized (eg. a cosmic ray artifact affecting only 1 pixel). This parameter has a Normal distribution for sources in each array, with mean zero and variance unity. Large values correspond to resolved sources and negative values to under-sized objects. The $\mathtt{mergedClassStat}$ parameter for objects in the region of the plot occupied by the extragalactic group typically has a value between 2 and 10.

We note that the classification of source image profiles as resolved or unresolved becomes unreliable near the sensitivity limits ($m_K \gtrsim 18$).

These results for the relatively uncrowded fields in the outer Galaxy are highly encouraging. However, the same cannot be said for much more crowded fields in the direction of the inner Galaxy. We noted in §3.2 that sources classified as spatially resolved ($\mathtt{mergedClass=+1}$) are sometimes merely unresolved stellar pairs. Such pairs are very common in crowded fields.

To test whether it is possible to identify external galaxies in crowded fields using the source catalogues, we visually inspected a crowded field located at $(l,b)=(30.2,1.2)$ The area of this field is 1 WFCAM tile (0.75 deg^2). Visual inspection of the 48 images (16 WFCAM arrays in 3 passbands) yielded 38 galaxies, 15 possible galaxies and one nebulous region. We refer to this selection as galaxies for brevity. The nebulous region is not listed in the source catalogues. Fifty two of the fifty three galaxies have $\mathtt{mergedClass=+1}$, corresponding to $\mathtt{pGalaxy} > 0.9$. By contrast, the field contains ∼1.6 million unique sources, of which 18% have $\mathtt{mergedClass=+1}$.

The (J-K) vs. K colour-magnitude diagram for this field (not shown) shows no clear separation between the galaxies and the sequence of reddened red clump giant stars in the field, even when the plot is restricted to sources with $\mathtt{mergedClass=+1}$. The galaxies satisfy the constraints $(J-K) > 1.7$ and $m_K < 16.5$, with a further restriction to $(J-K) > 1.9$ if we include only definite galaxies from the visual inspection. These cuts agree well with an intrinsic galaxy

colour of *(J-K)* = 1.0, subjected to the (total) extinction in this particular field.

Two further methods were used to attempt to separate the galaxies from stars: (i) the value of `K_1PetroMag - K_1AperMag3` (i.e. a measure of resolved (Petrosian) magnitude minus point source magnitude); and (ii) cuts based on the parameter `mergedClassStat`. We found that both methods can be used to reduce the number of stars with `mergedClass=+1` and similar colours and magnitudes to the galaxies. However, a cut based on either method requires us to throw away a significant fraction of the galaxies and the remaining contaminants still outnumber the the galaxies by a factor of at least 20.

We conclude that whilst in the outer Galaxy external galaxies can be easily found using the parameters in the catalogue, in crowded fields they offer no real advantage over a laborious visual search of the images. Better results may be achieved in the inner Galaxy at latitudes further from the mid-plane (up to the survey limit at b=±5°), when these data become available. We note that the extinction through the Galaxy (as defined by the DIRBE maps of Schlegel et al.1998) and the amount of source confusion and reddening varies greatly even within the 0.75 deg^2 field ($5.1 < A_V < 21.6$). Hence it may be possible to improve the discrimination between galaxies and red clump giant stars in future by adding a Galactic extinction parameter to **gpsSource** for each star (defined in a grid with a scale of a few arcminutes) and subtracting this from the measured extinction.

4.6 Spectrophotometric typing with optical and infrared data from IPHAS and the GPS

A limitation of the GPS data is that while the luminosity class of an individual field star can often be determined, it is not possible to estimate the spectral type in fields with significant reddening. This is because the reddening vector in the *(H-K) vs.(J-H)* two colour diagram runs almost parallel to the main sequence of stars with spectral types O-K, introducing a degeneracy between reddening and the intrinsic colours of the photosphere. The approximate reddening for individual sources can be estimated using the *(H-K)* colour, but only by assuming the all photospheres have the same intrinsic colour. A more precise reddening value can be detemined for YSOs by dereddening to the Classical T Tauri locus in the two colour diagram, as noted earlier, but the result is only valid for stars that are known to be YSOs.

We anticipate that this degeneracy can be broken for many of the brighter sources in the GPS by using optical data from IPHAS survey (Drew et al.2005; Sale et al., in prep). This survey covers the entire northern Galactic Plane down to Dec=-5° at $-5 < b < 5$ in the Sloan r', i' filters and an Hα filter. The survey is now almost complete and the IPHAS Initial Data Release (Gonzalez-Solares et al.2008) is now publically available, containing data from l=27 to l=117.

Work by members of the IPHAS team (Drew et al.2005) has shown that the IPHAS *(r'-i') vs. (r'-Hα)* two colour diagram can be used to break the degeneracy with extinction and estimate the approximate spectral type and distance of most field stars. However, this requires detection in the r' and Hα filters, which is not usually achieved in fields with
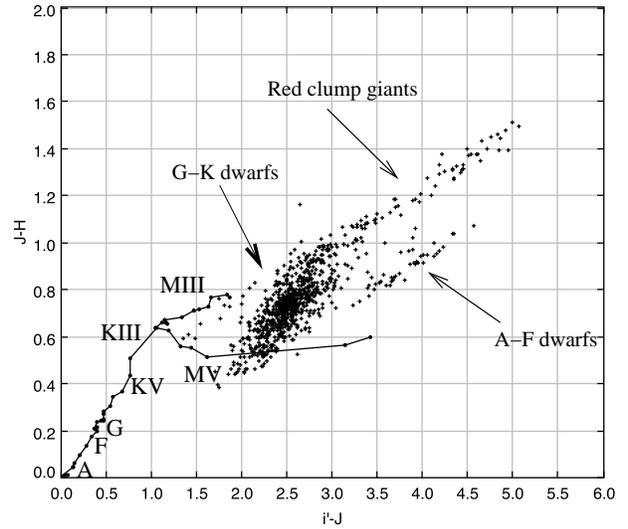

Figure 21. A combination of UKIDSS GPS and IPHAS data. This *(i'-J)* vs.*(J-H)* two colour diagram for the field at (l,b)=(31,0) allows us to distinguish distant early type dwarfs (located on the lower sequence of reddened stars) from nearby late type dwarfs (the main clump at *(i'-J)*=2.5 and distant red clump giants (the upper sequence of reddened stars). Data for unreddened stars from Hewett et al.(2006) are plotted at the lower left as filled symbols, linked by solid lines. The approximate location of unreddened main sequence spectral types is marked. Giants are redder than dwarfs in *(J-H)* at types K and M, leading to separate dwarf and giant sequences.

high reddening. Fortunately, i' fluxes will often be available for GPS sources even in fields with quite high reddening, since the IPHAS 5σ sensitivity limit is $i' \approx 20.7$ (Vega system).

In figure 21 we show an example of an IPHAS/GPS *(i'-J)* vs.*(J-H)* two colour diagram for the field with high reddening at (l,b)=(31,0) that was illustrated earlier in figure 5. The "PhotoObjBest" IPHAS catalogue, which contains sources that were observed in good photometric conditions and detected in all 3 IPHAS passbands, was used for the cross match. The scatter in the diagram has been reduced using cuts very similar to the "most reliable, low completeness" cuts used for the near infrared two colour diagrams (see §A3), including a restriction to sources with uncertainties <0.05 mag in i' and J. The two sequences of stars extending to the upper right of the diagram are dwarfs (lower sequence) and giants (upper sequence). The separation between the two sequences is cleaner than in the two colour diagram in figure 5 because the separation in the *(i'-J)* colour is ~1.25 magnitudes, which is far larger than the typical photometric uncertainties in this colour. That is not the case for the *(H-K)* colour used in figure 5, even though we restricted the selection to sources with uncertainties listed as <0.05 mag on each axis. The fundamental reason for the separation remains the different intrinsic *(J-H)* colours of the two populations, which is due to the gravity sensitivity of the *(J-H)* colour in the giants and the earlier spectral types of the dwarfs.

In addition to the improved dwarf/giant separation, a major benefit of figure 21 is the potential for spectrophotometric typing. The sources on the reddened dwarf branch

are almost entirely distant early type stars (spectral types A
and F). This can be seen by tracing the dwarf branch back to
where it would intersect with the unreddened main sequence
that is overplotted (using data from Hewett et al.2006). The
location of the dwarf branch is consistent with either red-
dened A-F type stars or M dwarfs. The latter can be ruled
out since they are not detected at large enough distances to
incur significant reddening. This interpretation is supported
by a Besançon model of the field which confirms that this
branch is composed of A and F type stars. (The model uses
the Cousins I filter rather than Sloan i' so it is not exactly
comparable and is therefore not shown).

The reddened dwarf sequence can also be traced back to
the lowest part of the main clump of stars near *(i'-J)*=2.5,
as would be expected for these intrinsically blue, early type
stars. The larger population of G and K type dwarfs is con-
tained in the clump of apparently bluer stars near *(i'-J)*=2.5
since these less luminous stars are not detected at sufficiently
large distances to suffer such high reddening. The clump
appears elongated from lower left to upper right, and is en-
tirely consistent with a reddened population of G and K
type main sequence stars that mostly have similar extinc-
tion. This sequence is sufficiently inclined to the reddening
vector to break the colour-reddening degeneracy and distin-
guish G-type stars from K-type stars. The extinction toward
stars in the G-K clump is A_V=4-5 magnitudes and the im-
plied distances are typically ∼1-2 kpc. The most distant red
clump giants in the plot have A_V≈9 magnitudes and im-
plied distances of ∼3.8 kpc. Stars that are 1-2 magnitudes
fainter in i' than those plotted, and therefore more distant,
could be detected by (i) cross matching with the IPHAS
"PhotoObj" catalogue rather than PhotoObjBest; and (ii)
including sources with larger photometric uncertainties. The
PhotoObj catalogue does not require detection in all three
IPHAS passbands for a star to be included.

ACKNOWLEDGEMENTS

APPENDIX A: GUIDE TO THE WFCAM SCIENCE ARCHIVE FOR GPS SCIENCE

A1 Fundamentals of the GPS data, archive structure and usage

In this guide to the GPS we do not assume that the reader
has previously used the WSA, nor any knowledge of SQL
(the Structured Query Language which is used to con-
struct and interrogate the WSA). There is extensive general
UKIDSS documentation at the WSA and CASU websites

so this guide focuses on information that is useful for GPS
science.

A1.1 Multiframes: the basic unit of data

WFCAM has four spatially separated 2048×2048 HAWAII
2 infrared array detectors laid out in a 2×2 square pat-
tern. Each array covers a 13.65×13.65 arcminute field of
view and the gaps between them are 12.83 arcmin, or 94%
of a detector width. A single observation therefore covers a
partially filled area of sky known as a "multiframe". In the
GPS, a series of four slightly overlapping multiframes with
offsets of 13.24 arcmin in RA and Dec is used to produced a
filled "tile" with an area of 0.75 deg^2. The multiframe (not
the tile) is the fundamental unit around which the WSA is
designed. Every multiframe has a reference number in the
WSA. By contrast, the tiles are not catalogued. The WF-
CAM arrays are always oriented approximately north-south
(to within ∼ 1°), so the GPS tiles the Plane in strips of
constant Declination, always slightly overfilling the desired
Galactic latitude boundaries with array corners and edges.

The term multiframe is also applied to a coadded se-
quence of observations with spatial offsets of a few arcsec
(see A1.2). Every pipeline processed multiframe is stored in
the WSA (both individual integrations and a coadded series
of observations). However, only the coadded images have
associated source catalogues (see A1.4).

A1.2 GPS observation sequence

All GPS data are taken with a 2×2 "microstepping" se-
quence in order to fully sample the spatial resolution of the
image in the focal plane, which is frequently < 2 pixels Full
Width Half Maximum, i.e. < 0.8 arcsec. The microsteps used
in the GPS are spatial shifts of 4.6 arcsec, which is approx-
imately 11.5 pixels (depending on location within the focal
plane). This "N+0.5" microstepping allows the four separate
images to be interleaved in order to produce images with a
0.2 arcsec pixel scale. After going through the microsteps,
the telescope is then moved through 3.2 arcsec (8 pixels)
in RA and/or Dec before repeating the microstep sequence.
This jitter procedure provides independent pixels to aid the
removal of any bad pixels that were not included in the bad
pixel mask. From DR1 onward the number of jitters is two,
so the observations comprise eight individual exposures of
duration 10 s, 10 s and 5 s to make up total on source inte-
gration times of 80 s, 80 s and 40 s in the J, H and K filters
respectively. In the EDR four jitters were used for the J and
H bandpass observations, with 5 s individual integrations.
The number was reduced to two in order to improve observ-
ing efficiency. Observations in the H$_2$ filter used two jitters
in all data releases, with eight individual exposures of 20 s
making up the on source integration time of 160 s.

A1.3 GPS images in the WSA

The multiframe images are stored as FITS images with a
header unit and four image extensions, one for each spa-
tially separated array. There are three main types of reduced
GPS multiframe image. (1) Individual integrations, which
are listed as *normal* multiframes and have a pixel scale of

0.4 arcsec. (2) Interleaved images, listed as *leav* multiframes, which are formed from four images taken in the microstepping sequence and have a 0.2 arcsec pixel scale. (3) Final coadded images (also with a 0.2 arcsec pixel scale) that are formed by coadding two or more interleaved images and are listed as *leavstack* multiframes in the WSA. For most purposes GPS users will only need to use the *leavstack* multiframes.

The user can make a list of the GPS multiframe images for download, and view high quality jpeg preview images, by selecting "Archive Listing" at the top level of the WSA and then selecting the GPS from the Programme drop down menu. The user will normally use the most recent UKIDSS release by default but there are also options to use either the earlier releases (which are a subset of the most recent release but can be searched slightly more quickly) or "WSA" in order to include images which failed quality control but may still be useful for some scientific purposes. The three types of reduced science image described above will be returned if the default settings of "object" in the Observation Type drop down menu and "all" in the Frame Type drop down menu are used. If the latter menu is set to "stack" then only *leavstack* images will be returned. The desired images can then be selected by date, by filter and by Equatorial coordinates (FK5 system, defined by a rectangular box). Two additional types of GPS image are the H_2-K *difference* images provided for the off-plane TAP region and *confidence* images, which exist for all *leav* and *leavstack* images and can be used to check for defects in the data. The *difference* images are scaled by the filter width to remove sources with a flat continuum. The *confidence* images are only returned if the Observation Type is changed from "object" to "confidence". Pixels in the *confidence* images have a median value of 100. Lower values correspond to either reduced sensitivity measured in the flat fields, bad pixels, hot pixels detected in the darks or saturated pixels. Other image types from the reduction process, such as *Sky* images and *Dark* images can also be obtained with the appropriate setting of the Observation Type. *Sky* images are generally constructed using a sequence of frames taken throughout the night. These may be useful in order to assess the quality of the background subtraction in Galactic plane regions with bright nebulosity.

The coordinates returned by the Archive Listing for a multiframe are those of the centre of the WFCAM focal plane, which lies between the four spatially separated arrays and is therefore a region with no data! Hence if the full array image nearest a particular location is desired, it is necessary to either use the Image tools described below to find the multiframe number or else search for all images in a box $0.8°$ wide, centred on the target location, to find the desired one.

More user friendly image access is provided by the "GetImage", "MultiGetimage" and "Region Search" tools at the top level of the WSA, and via links from the **gpsSource** catalogue entries described below. The "GetImage" tool allows the user to find and download cut-out images in all available filters, centred on the desired Galactic or Equatorial coordinates. The image size is limited by the user-specified dimensions or by the boundaries of the 13.6 arcminute array field of view. There may be more than one image in each filter if the coordinates lie in the small over-

lap region at the edge of an array, or if the field has been observed more than once. Second epoch observations have not yet occurred for the GPS, except when a field has been repeated by the observer to ensure the data quality satisfies the survey requirements. The "MultiGetimage" tool is similar but it allows a large number of images to be downloaded in a single filter, each centred around a list of Equatorial coordinates provided by the user. The "Region Search" is described below.

The UKIDSS astrometric solutions are determined by fitting to numerous 2MASS stars in the field of each separate science array, as noted in §2. The typical precision of the solution is 0.09 arcsec, as determined from the r.m.s. residuals to the fit, but there is some variation. The value of the r.m.s. residual for a given science detector array is given by the STDCRMS parameter. This parameter is given in the image headers for each array. It is also accessible via the **CurrentAstrometry** table in the WSA, which can be viewed using a FreeForm SQL query (see §A1.4).

A1.4 GPS catalogues

Most users will wish to use the SQL source catalogues to search for astronomical objects. **gpsSource** is the most commonly used catalogue. It is the merged catalogue containing most of the important data for all sources detected in at least one of the J, H and K passbands. The pairing scheme starts with the shortest available wavelength (the J band if the data are available, or the H band if not) and searches for counterparts in the H band and then the K band that are located <1 arcsec from the J band detection. Sources are only merged as a single entry in **gpsSource** if each is the closest match to the other at all wavelengths. The epoch of observation of a star in **gpsSource** in each filter can be determined by clicking on the entry in the "getMFlink" column in the table, which will provide 1×1 arcminute images centred on the star, with associated dates and times. The other main table, **gpsDetection**, contains all the information for all sources detected in any passband but with no association between detections of the same object in different filters. While **gpsSource** is more convenient to use, the caveats are: (i) it includes only a subset of the photometric aperture sizes that are available in **gpsDetection** or the FITS binary catalogues; and (ii) in releases from DR3 onward, most of the extragalactic flux extimates such as Petrosian magnitude are no included. The details of how to write an SQL query to extract these missing attributes from the **gpsDetection** table are given in the "SQL Cookbook" at the top level of the WSA.

The available columns or "attributes" in each table are seen when conducting a Menu Query (see below), which optionally provides a one line description of each attribute. We recommend that the user reads the more detailed entries for the **gpsSource** and **gpsDetection** parameters in the "Schema Browser" (accessible from the WSA top level) under "WSA UKIDSS" and then "Tables".

The GPS SQL catalogues can be searched using the Region Search, the Menu Query (recommended for new users) or the Freeform SQL page, all of which are accessible from the top level of the WSA. When using these tools, users of the DR2 release and subsequent releases have an option (in the drop down menu of tables) to view a subset

of **gpsSource** which includes only areas which are complete in all three filters. This can slightly improve search speeds where the desired area is known to be complete (e.g. from an Archive Listing). If previous data releases are being searched, the user can similarly search a dataset with full filter coverage by selecting e.g. the DR1 database, as opposed to the larger DR1PLUS database.

The simplest way to search the **gpsSource** table is with the Region Search. This enables a simple search of a circular area around the desired Equatorial or Galactic coodinates and it returns all information in the table for every object therein. In addition, the sources listed can be clicked on to provide jpeg and FITS format cut-out images around their location, in all available filters (similar to the GetImage results).

More flexible and sophisticated queries can be made with the Menu Query or a FreeForm SQL query. Menu Queries are constructed by clicking boxes. They return only the desired attributes and restrict their values (e.g. magnitudes, colours, coordinates etc.) in order to refine a search. This is especially important for the GPS because a maximum of only 15 million data entries can be returned in a single query (e.g. 1.5 million sources with 10 data attributes each), which can quickly be exceeded when searching more than a square degree in crowded fields. The **gpsSource** attributes that are highlighted in the Menu Query list have their own indices in the table, which means that searches based on these parameters will proceed much more rapidly than those which do not. Hence searches based on e.g. specified coordinates (Equatorial or Galactic) and a range of magnitudes will proceed rapidly if the prferred photometric aperture (`AperMag3`, see below) is used, but will take much longer if a different aperture size is used. Again, this is a serious issue since the size of the GPS catalogues means that searches can often time out (the maximum duration is presently 80 minutes) when searches are based on non-highlighted attributes. Merely including non-highlighted attributes among the data to be returned (as opposed to specifying a range of values) does not cause this problem.

FreeForm SQL queries can perform the same tasks as a Menu Query and also manipulate the data returned from the table or operate on two or more tables (e.g. GPS data and Spitzer GLIMPSE data) to produce more complicated outputs. Menu Queries are transformed into ASCII format SQL queries before processing. A useful feature of the WSA is that this SQL query can be viewed using the "Show and Edit SQL" button during a Menu Query. This enables the user to learn how to perform basic FreeForm SQL queries with no prior knowledge of the language. The SQL Cookbook provides further training.

A list of FITS binary source catalogues associated with individual coadded multiframe images (*leavstacks*) is provided along with the image lists described in §A1.3 in an Archive Listing. They may be viewed with freely available software such as FV (FitsViewer). These catalogues contain only single filter data and source fluxes within the various apertures are given in data numbers (normalised to the exposure time of individual frames on sky) rather than magnitudes. The catalogue headers include the aperture corrections, photometric zero points, airmass and the exposure times (for the individual frames on sky), so it is straightforward to calculate magnitudes or to conduct additional

photometry, e.g. on very faint sources which may have been missed by the source detection algorithm and are therefore not in the source catalogues. We note that the FITS binary catalogues have less precise R.A. and Dec coordinates than the SQL source catalogues, owing to a limitation on the number of data bits which corresponds to a precision of $\sim$0.36 arcsec. However, the exact coordinates can be recovered using the precise X, Y array coordinates given for each source and the WCS information in the catalogue FITS headers. Details of the columns in the FITS binary catalogues (which provide additional information relevant to the SQL source catalogues) are available from the CASU website (Irwin et al.2005) and in Irwin et al.(2008).

A1.5 Simultaneous multi-aperture fitting photometry and `AperMag3`

The WFCAM pipeline performs aperture photometry, as opposed to profile fitting photometry. However, any overlapping apertures are simultaneously fitted and the fluxes in areas of overlap are assigned to each target in proportion to the total flux within each aperture. This generally produces good photometry even in the crowded GPS fields (see A3), though there will be cases where the photometry is imperfect, such as faint sources on the wings of a bright or saturated star. We note that profile fitting photometry may be included in the final processing of all UKIDSS data when the survey is finished, but tests with an algorithm designed for the irregular image profiles often generated by ground based microstepped data have shown no significant gain in precision.

Photometry is output for a series of circular apertures, for which consecutive aperture numbers have a ratio of $\sqrt{2}$ in diameter. The smallest aperture, `AperMag1`, has a diameter of 1 arcsec. The default aperture that is used for GPS point source colours in **gpsSource** is `AperMag3`, which has a diameter of 2 arcsec. Only `AperMag3, AperMag4 and AperMag6` and the much larger `Hallmag` aperture (which is a measure of the total flux from each source) are available in **gpsSource** in the existing data releases (though all apertures are available in **gpsDetection**). We recommend that `AperMag3` is used for most GPS science unless there is good reason to desire a smaller or larger aperture. For future UKIDSS releases it is planned to change the available apertures in **gpsSource** to `AperMag1, AperMag3 and AperMag4`, with the rationale that the smaller aperture yields more reliable photometry in the most crowded fields and the slightly larger aperture will sometimes yield more precise photometry in the off-plane TAP region, where relatively poor seeing is accepted.

A2 Limitations and unusual features of the GPS data

Here we describe some peculiar features of the GPS data which the user may notice but whose origin may not be immediately obvious.

• In many images the profiles of stars in the *leav* and *leavstack* images may appear to be slightly "speckled" with departures from the smooth monotonic image profiles usually seen in astronomical data. This is due to the changes

in the natural seeing during the microstepping procedure referred to in A1.2, which can cause adjacent rows and columns to show significant differences in flux. Comparison of fields with and without this effect have shown that it has no significant effect on photometric precision.

• Electronic cross talk between adjacent array read out channels causes the appearance of spurious sources located at multiples of 128 pixels (51.2 arcsec) away from all bright stars along the axis of array readout (which is oriented differently for each quadrant of an array). This is a general feature of Hawaii 2 arrays that is most serious for pixels which are close to saturation (> 30000 DN) in the WSA images. Note that the separation 128N pixels becomes 256N pixels in the coadded and interleaved *leavstack* images. All data in the DR2 release benefit from a cross-talk removal procedure which has reduced the problem. Hovever, the procedure is imperfect so some artifacts remain. This is particularly so in regions with spatially variable background, where a flaw in the procedure actually generated additional cross talk artifacts that do not always lie 128N pixels from a bright star. Owing to this error some images of regions with large gradients in the background were removed from DR2, including several H band images near the Galactic Centre. The error will be fixed from DR3 onward and the lost images will be recovered. The archive also addresses the cross talk problem from the DR2 release onward, but in the catalogues rather than the images. Possible cross talk artifacts are flagged in the data given in the `ppErrbits` columns in **gpsSource** and **gpsDetection**. This identifies almost all cross talk artifacts at 128N pixels from a bright star by using the 2MASS Point Source Catalogue. Usage of the `ppErrbits` flags to remove suspect data is described in A3.

The brighter artifacts can be seen to be spurious since they have positive counts on one side of the profile and negative counts on the other (relative to the sky level). This is because the cross talk artifacts are related to the spatial derivative of the profile of the bright star that generated them, in the readout direction. Fainter stars can sometimes produce artifacts which look more like real stars (and generally have similar colours). It is advisable to guard against this by checking the images for bright stars near objects of interest. Over-saturated stars produce larger, obviously non-stellar artifacts with a ring-like structure.

• Saturated stars have $\gtrsim 35000$ counts in *leavstack* images, but the centre of an oversaturated star has a lower count level (often below the sky background). This is a general feature of data taken with near infrared arrays in the correlated double sampling mode (CDS). Saturated stars exist in most GPS fields. They are usually included in the source catalogues but the fluxes given are not meaningful. Again, the `ppErrbits` column in the catalogues can be used to efficiently remove these bad data, in this case by requiring e.g. `JppErrbits`<65536 to ensure that a source is not saturated at J band. Conservatively, it is safer to use 2MASS at m_K<12.0, m_H<12.75, m_J<13.25, though the typical saturation limits are ~0.5 magnitudes brighter than this. The `ppErrbits` parameters can be used to find the precise limits for each field in each filter, using the threshold value quoted above. Heavily oversaturated stars cause multiple spurious detections in each filter (and in **gpsSource**), since the saturated region is larger than the size of the stellar image profile used by the pipeline source detection algorithm. These are

often listed in the archive as resolved sources rather than stars (i.e. `mergedclass=+1`).

• Photometric errors are generally under-estimated. The photometric errors given in magnitudes and colours are only notional internal errors (excluding calibration uncertainty) that are based on source counts in the apertures, the Full-Width-Half-Maximum (FWHM) of the image and the standard deviation of the background flux. A plot of errors vs. magnitude yields a single smooth curve for fields contained within a single WFCAM array. The WSA is similar to the 2MASS Point Source Catalogue in this respect. The given error systematically underestimates the true error by a factor of ~1.2, owing to the inter-pixel capacitance of the WFCAM arrays. This phenomenon reduces the noise estimate derived from a measure of the local standard deviation by this factor by causing inter-pixel correlation of the count values (Irwin et al.2008). Hence sources with photometric uncertainties of 0.20 magnitudes in the archive are in fact usually closer to 4σ detections than 5σ detections. Additionally, errors specific to individual sources are not included in the error budget: e.g. bad pixels, the presence of adjacent stars or cross talk artifacts, or small scale spatial variations in sky background. Finally, the CASU pipeline is designed to deliver an absolute photometric precision of ~0.02 mag for sources with a high signal to noise ratio. (The uncertainty in the photometric calibration is discussed below). Therefore users should not take seriously the millimagnitude uncertainties that are quoted for bright stars. When studying a particular source users should inspect the image data (and perhaps also the *confidence Images*) to be sure that the given error is meaningful.

• Nebulosity can also lead to photometric errors, since the sky background is evaluated with a relatively coarse grid in each field (typically in 25 arcsec grid cells). A more sophisticated method of measuring the background on smaller spatial scales in nebulous regions has been developed by M.Irwin in order to improve the photometry but it will not be implemented in the WSA until DR5. More seriously, the source detection algorithm fails in regions of very bright nebulosity, since the nebula is interpreted as a single extended source. At present this effect has been seen only in parts of the M17 star formation region (see §4.2) which is one of the largest regions of bright nebulosity in the sky. In such regions, it is necessary at present for users to do their own photometry (see §4.2)

Finally, we provide the extinction dependent 2MASS-WFCAM photometric transformations that are used to generate the photometric zero points for each detector, as noted in §2.

$$J = J_{2M} - 0.065(J_{2M} - H_{2M}) + 0.015E(B - V)$$

$$H = H_{2M} + 0.07(J_{2M} - H_{2M}) + 0.005E(B - V) - 0.03$$

$$K = K_{2M} + 0.01(J_{2M} - K_{2M}) + 0.005E(B - V)$$

The $E(B - V)$ colour excesses are computed using the prescription of Bonifacio et al.(2000), from the data of Schlegel et al. (1998). Since the extinction terms are small ($E(B - V)$=3 corresponds to 9 magnitudes of visual extinction for a typical interstellar reddening law), differential extinction across each detector is usually insufficient to contribute significantly to the uncertainty in the zero points, as

measured by the internal scatter amongst the bright 2MASS sources that are used. (The uncertainties in the zero points are included in the image headers and the FITS binary catalogue headers.) However, a small number of fields exist where spatially variable extinction causes significantly increased uncertainty in the calculated zero points. This should be borne in mind if the data are used to investigate e.g. possible spatial variations in the near infrared extinction law in star formation regions.

A3   Optimising the results of GPS catalogue searches

Here we present three different choices of catalogue parameters that are likely to be useful to generate different types of source list, ranging from a complete but unreliable selection of the stellar sources in a region to a highly reliable but seriously incomplete selection. A fourth option is to use **reliableGpsPointSource** in a Freeform SQL query instead of **gpsSource**. This "VIEW" of the source table is simpler than the methods described below but less effective. Details of its contents are available under "Schema Browser" at the WSA.

Generating a complete list of unique Galactic sources is a little more complicated than simply returning all sources in a region of the sky. This is for two reasons. (1) **gpsSource** contains sources classified as "noise", via the attribute "mergedClass $=0$", in addition to the more numerous real sources which are variously classified as stars (**mergedClass** $=-1$), probable stars (**mergedClass** $=-2$), galaxies (**mergedClass**$=+1$) and probable galaxies (**mergedClass** $=-3$), on the basis of the image profile. The UKIDSS philosophy is to include in the archive all data that might be useful. However, we recommend that sources classified as noise be excluded from GPS searches, since most of them are not real sources, and they would inflate the star counts in any given field by $\sim 10\%$. In general this will lead to a more accurate star count in any given field than a search on all types of source, at the price of excluding only a very small number of real sources. By contrast, it is necessary to include "galaxies" and "probable galaxies" in a complete search, since many of these (in fact most of them in crowded fields) are marginally resolved pairs of stars which have been misclassified in **gpsSource**. (2) Sources located in the regions of overlap between different arrays in a WFCAM tile are duplicated in the WSA. These duplicates can be identified and removed using the *PriOrSec* attribute, which describes Primary or Secondary detections (see Hambly et al.2008). This consideration also affects $\sim 10\%$ of sources.

An illustrative SQL query to return a selection of useful attributes for the complete list of real unique sources located near $l = 31$, $b = 0$ is given below. Comment lines in the query begin with "/*" and end with "*/".

```
SELECT sourceID, ra, dec, l, b, jmhPnt,
    jmhPntErr, hmk_1Pnt, hmk_1PntErr,
    mergedClass, pStar, jAperMag3,
    jAperMag3Err, hAperMag3, hAperMag3Err,
    k_1AperMag3,k_1AperMag3Err
FROM gpsSource
WHERE l BETWEEN 30.9 AND 31.1
    AND b BETWEEN -0.1 AND 0.1
```

```
/* Exclude detections classified as noise*/
    AND mergedClass != 0
/* Exclude multiple detections of the same
source /*
    AND (PriOrSec=0 OR PriOrSec=framesetID)
```

It should be noted that this query must be typed or copied into the Freeform SQL interface, since the last line cannot be entered with the simple mathematical operators available in the Menu Query interface. The two colour diagram for the complete search at these coordinates is shown in figure A1(a).

It is frequently desirable to restrict the sample to sources with small photometric errors, in order to identify the main stellar populations more easily in two colour and colour magnitude diagrams. A restricted search can be done entirely with the WSA but since the user will often wish to vary the search parameters while investigating the data it is often preferable to download the results of a complete search and then alter the parameters interactively. This can be done by loading the data into a suitable software package. We strongly recommend TOPCAT, a user friendly software package designed to manipulate and display data tables written in a variety of Virtual Observatory and text formats.[4].

The following SQL query returns all the parameters needed to construct a more reliable but less complete photometric sample:

```
SELECT sourceID, ra, dec, l, b, jmhPnt,
    jmhPntErr, hmk_1Pnt, hmk_1PntErr,
    mergedClass, pStar, jAperMag3,
    jAperMag3Err, jEll, jppErrBits, jXi, jEta,
    hAperMag3, hAperMag3Err, hEll, hppErrBits,
    hXi, hEta, k_1AperMag3, k_1AperMag3Err,
    k_1Ell, k_1ppErrBits, k_1Xi, k_1Eta
FROM gpsSource
WHERE l BETWEEN 30.9 AND 31.1
    AND b BETWEEN -0.1 AND 0.1
/* Exclude noise detections */
    AND mergedClass != 0
/* Exclude multiple detections of the same
source /*
    AND (PriOrSec=0 OR PriOrSec=framesetID)
```

Figure A1(b) is the two colour diagram for the subset of this download with errors < 0.05 mag on each axis. This was defined in TOPCAT by the expression "abs(**jmhPntErr**)<0.05 && abs(**hmk_1PntErr**)<0.05", where "abs" is the modulus operator and "&&" is the logical operator AND. (We note that column numbers can be used in TOPCAT instead of parameter names for brevity). The majority of the sources are located in a band running from the lower left to the upper right, caused by the reddening of the main sequence and giant star populations. However, a large number of photometric outliers are apparent and some sources lie outside the boundaries of the plot. A smaller subsample with better photometry and $> 50\%$ completeness can be selected from the download

---

[4] TOPCAT is available from www.starlink.ac.uk/topcat
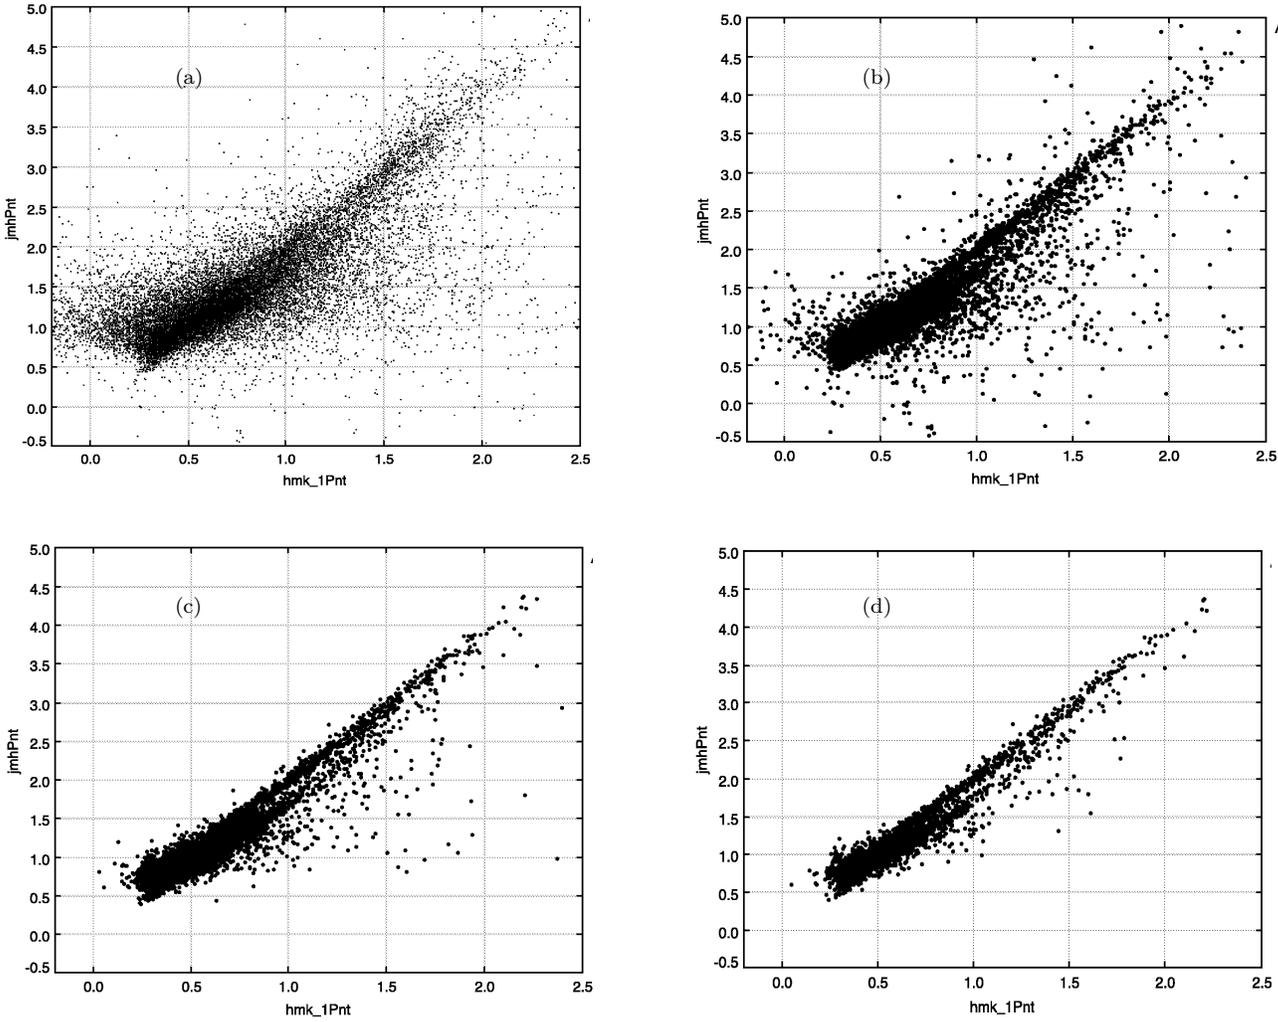

Figure A1. *(J-H) vs.(H-K)* two colour diagrams for a 0.04 deg^2 area at (l,b)=(31,0) illustrate the trade off between completeness and reliability. (a) Complete selection of 51780 sources, excluding only "noise" sources. (b) Selection of the 8183 sources from plot (a) with errors <0.05 mag in each colour. (c) Selection of 5914 sources with colour errors <0.05 mag, stellar image profiles, and more reliable photometry. (d) Selection of 2787 sources with colour errors <0.05 mag, stellar image profiles, and the most reliable photometry.

with the following additional cuts (in TOPCAT format):

```
pstar >0.99 && jppErrbits <256 && hppErrbits
<256 && k_1ppErrbits <256
```

The "`pstar`" parameter is the WSA estimate of the probability that the source is a star, as opposed to a galaxy, or noise. `pstar`=0.9 is the minimum value for a source to be classified as a star (`mergedClass`=-1), as opposed to e.g. a probable star or galaxy. In practice this selection helps to remove close stellar pairs that are resolved in only one or two of the three passbands. The "`ppErrbits`" parameters in each waveband can be used to identify sources which are either cross talk artifacts (see A2) or stars with less reliable photometry due to saturation, deblending, bad pixels or location at the extreme edge of the detector. The `ppErrbits` parameters are 16 byte integers (values from 0 to 65535). The least significant byte (`ppErrbits`<256) contains infor-

mation on minor issues that are unlikely to greatly affect the photometry: bad pixels within the 2 arcsec `Apermag3` aperture and whether the sources is deblended. The more significant bytes are populated (i.e.`ppErrbits`≥256) if there are more serious issues such as saturation, cross talk artefacts, or loaction within one jitter position of an array boundary. A fuller description is given in the WSA. We note that the alternative "`psat`" parameter for saturation probability is not functional at present in the WSA. The corresponding plot in figure A1(c) is much cleaner: most of the unresolved stellar pairs have been removed by the `pstar` selection and numerous saturated stars and their associated spurious multiple detections have been removed by the `ppErrbits` selection. In this case the completeness of the sample is 72%, relative to figure A1(b). The vertical separation between the reddened populations of dwarfs and giant is now readily apparent at *(J-H)*>1.75. The giants have ∼0.25 mag larger *(J-H)* colours than the dwarfs.

A sample with still more reliable photometry, but with lower completeness, can be defined as follows:

```
pstar > 0.99 && jppErrbits < 256 && hppErrbits
< 256 && k_1ppErrbits < 256 &&
sqrt(hXi*hXi + hEta*hEta)<0.3 &&
sqrt(k_1Xi*k_1Xi + k_1Eta*k_1Eta)<0.3 &&
jEll<0.2 && hEll<0.2 && k_1Ell<0.2
```

This is our "most reliable, low completeness" selection used in the two colour diagrams earlier in §3. The completeness of this selection is also typically $> 50\%$ in the less crowded parts of the GPS but is usually only 25-50% for fields near the mid-plane in the first quadrant. The "Ell" parameters give the ellipticity, which can be used to remove unresolved stellar pairs in a similar manner to `pstar`. The "Xi" and "Eta" parameters are the distances in arcseconds of each detection from the shortest wavelength detection, in RA and Dec respectively. The maximum pair matching radius is 1 arcsec for the GPS, but since the typical separation of genuine matches is $\lesssim 0.2$ arcsec, these parameters can also be used to eliminate unresolved binaries and other false matches. Figure A1(d) shows the corresponding plot, which is now only 34% complete relative to figure A1(b). Only a few sources with poor photometry now remain.
